Contents

1. Overview	1-1
Introduction by Example	1-1
Arrays	1-3
Origins of APL	1-4
Development Related to Array Processing	1-5
Interpretive Basis for APL	1-6
2. Grammar	2-1
APL Syntax	2-1
Syntactic Classes	2-1
Evaluation	2-3
Order of Execution	2-3
Ruthlessly Consistent Order of Execution	2-4
Infix Notation	2-4
Ambivalence	2-4
Niladic, Monadic, and Dyadic Use	2-5
Grouping	2-5
Tree Structure of a Sentence	2-6
Left-to-Right and Leaf-to-Root	2-7
Precedence of Verbs, Adverbs, and Conjunctions	2-7
Precedence in a Sentence with Adverbs or Conjunctions	2-8
Other Mechanisms of Grouping	2-9
Brackets Group in the Same Way as Parentheses	2-9
Semicolon Is a Separator	2-10
Other Punctuation	2-11
Colon and Label	2-11
Lamp and Comment	2-12
Arrays	2-12
Types of Nouns	2-13
No Declarations	2-13
Input Modes	2-13
Analysis of an Input Line	2-14
Preliminary Checks for) and V	2-14
Scanning the Line for Quotes and Comments	2-15
Dividing the Line into Sentences	2-16

Types of Sentences	2-16
Dividing a Sentence into Words	2-16
Multi-character Words	2-17
Blanks	2-17
Scanning Strategy for Locating Words	2-18
Numeric Constants	2-18
Complex and Exponential Number Formats	2-19
List Constants	2-19
Names	2-20
Assigning Words in a Sentence to Syntactic Classes	2-21

3. Nouns and Pronouns **3-1**

Rank and Shape	3-1
Reporting Shape and Rank	3-2
Arrays and Cells	3-2
Complementary Partition	3-4
Major Cells	3-5
Infinite Rank	3-5

Types of Noun Items	3-5
Homogeneity of Arrays	3-5
Empty Arrays	3-5
Numbers	3-6
Internal Representations of Numbers	3-6
Character Data	3-8
APL Character Set	3-8
Boxed Arrays	3-10
Partitioning	3-10
Display of Boxes	3-11
Packages	3-12

Input and Output	3-13
Constants	3-13
Creating Higher-Rank Arrays	3-14
Creating the Value of a Box	3-15

Display of Nouns	3-15
Position and Spacing in an Array of Boxes	3-16
Separating Successive Columns of a Numeric Array	3-17
Separating Successive Planes of Higher-Rank Arrays	3-17
Folding Wide Displays	3-17
Folding a Character Array	3-18

Folding a Numeric List	3-18
Folding a Numeric Table or Higher-Rank Array	3-18
Folding an Array of Boxes	3-19
Display of an Empty Array	3-19

Interface Nouns: \square and \square	3-19
Evaluated Input	3-19
Input in Response to \square	3-20
Character Input	3-21
Escape from \square -Input and \square -Input	3-22
Explicit Output from \square and \square	3-22
Folding of \square Output	3-23
Input on the Same Line as the Character Prompt	3-23
Discarding the Prompt	3-24

4. Naming Nouns and Verbs

\leftarrow Copula

Workspace: The Universe of Names

Localization of Names

Reassignment and Name Conflicts

Names for User-Defined Objects

Indexed Assignment

The Result of Assignment

Multiple Assignment

Sentences Producing No Display

Other Mechanisms that Produce Named Objects

5. Verbs

Default Argument Ranks

Agreement	5-2
Scalar Verbs	5-2
Extending the Empty Frame	5-3
Unbounded Rank	5-3
Unspecified Rank	5-3
Reduction and Identity Elements	5-4
Result Rank and Shape	5-7
Verb Definitions	5-8
+ - * ÷ : Plus, Minus, Times, Divide	5-8
Dyads + - * ÷	5-8
Cartesian Representation of Complex Product	5-8
Polar Representation of Complex Product	5-9
Division by Zero	5-9
Monad +	5-9
Monad -	5-10
Monad *	5-10
Monad ÷	5-10
⊞ : Matrix Inverse; Matrix Divide	5-11
Monad ⊞	5-11
Dyad ⊞	5-11
Frame and Cells with Dyad ⊞	5-13
* ● : Power, Log	5-14
Monads * and ●	5-14
Dyad *	5-15
Dyad ●	5-16
○ : Circle Verbs	5-17
Monad ○	5-17
Dyad ○	5-17

Selection of Function by Left Argument of O.....	5-18
Geometric View of the Pythagorean and Circular Functions.....	5-18
Geometric View of the Hyperbolic Functions.....	5-19
Representations of Complex Numbers.....	5-21
\lceil : Floor, Ceiling; Max, Min.....	5-22
Monads \lceil and \lceil	5-22
Tolerant Floor and Ceiling.....	5-23
Floor of a Complex Number.....	5-23
Dyads \lceil and \lceil	5-25
$ $: Magnitude; Residue.....	5-26
Monad $ $	5-26
Dyad $ $	5-26
$!$: Factorial; Combinations.....	5-28
Monad $!$	5-28
Dyad $!$	5-29
$?$: Roll; Deal.....	5-30
Monad $?$	5-30
Dyad $?$	5-30
Argument Rank.....	5-30
Pseudo-random Algorithm and Or2.....	5-31
$< >$: Box, Open; Link.....	5-32
Monad $>$	5-33
Tolerant Open.....	5-33
Fill Elements.....	5-34
Monad $<$	5-35
Dyad $<$	5-35
$< >$: Less; Greater.....	5-37
\leq : Less than or Equal.....	5-37
\geq : Greater than or Equal.....	5-37
$= \neq$: Nubsieve; Equal, Unequal.....	5-38
Monad \neq	5-38
Dyad $=$	5-40
Tolerant Comparison of Real Numbers.....	5-40

Dyad \neq	5-41
\equiv : Match	5-41
\sim : Not	5-42
$\wedge \vee \star \div$: LCM, GCD; And, Or; Nand, Nor	5-42
Boolean Arguments	5-42
Non-Boolean Arguments	5-43
Tolerant GCD and LCM	5-44
$\triangleright \triangleleft$: Right, Left; Dex, Lev	5-44
Dyads \triangleright and \triangleleft	5-44
$\tau \downarrow$: Encode; Decode	5-46
Dyad τ	5-46
Relation Between Representation and Residue	5-46
Higher-Rank Arguments to τ	5-48
Forcing Representation Cells to the Last Axis	5-49
Dyad \downarrow	5-50
Item Left Argument	5-50
Higher-Rank Right Argument	5-51
Higher-Rank Left Argument	5-51
Length-1 Base	5-51
Forcing Representation Cells to the Last Axis	5-52
Limitations on Inverse	5-52
Evaluation of Polynomials	5-53
∇ : Format	5-53
Default Display	5-53
Monad ∇	5-54
Array-wide Format vs. Item-by-Item Format	5-55
Choice of Fixed-Point or Exponential Format for Real Numbers	5-55
Mixed Formats in Representation of a List	5-56
Appearance of Fixed-Point Format	5-56
Appearance of Exponential Format	5-57
Appearance of Complex Format	5-58
Field Width in Tables	5-58
Blanks Between Columns	5-59
Examples of Monad ∇	5-59
Separation Between Planes of Higher-Rank Arrays	5-60
Format of an Array of Boxes	5-60
Effect of \square s on Position and Spacing of Boxes	5-61
Position: The First Two Elements of \square s	5-62

Spacing: The Last Two Elements of Ops	5-62
Dyad ∇	5-63
Dyad ∇ with Empty α	5-64
Dyad ∇ with Numeric α	5-64
Fixed-Point Representation	5-64
Exponential Representation	5-66
Dyad ∇ with Character α	5-67
Numeric Fields within the Pattern	5-67
Decorators within the Pattern	5-68
Treatment of the Decimal Point and Decimal Digits	5-69
Treatment of the Sign	5-69
Alternative Conventions Regarding Decimal Point and Grouping	5-70
Dot and Comma	5-71
Significance of the Control Digits 0 to 9	5-72
Effect of $\square f c$ on ∇ Format by Example	5-77
Δ : Execute	5-78
Result of $\Delta \omega$	5-79
Display of Result	5-79
Evaluation of Multiple Sentences	5-79
Occurrence in the State Indicator	5-80
Branch within Execute	5-80
Errors Encountered During Execution	5-81
\square signal within Execute	5-81
τ , : Table, Ravel; Join	5-82
Monads , and τ	5-82
Dyads , and τ	5-85
Restrictions on the Domains of τ or ,	5-85
Shape of Arguments and Result	5-85
Joining Two Arrays Along a New Axis	5-87
Joined Arrays May Differ in Rank by 1	5-90
Joining an Item to an Array	5-90
Joining Modified by Bracket-Axis Notation	5-91
\ominus ϕ : Reverse, Upset; Rotate, Rowel	5-92
Monads \ominus and ϕ	5-92
Dyads ϕ and \ominus	5-93
ϕ and \ominus Modified by Bracket-Axis	5-95
Upset and Rowel in Terms of Rotate and Reverse	5-95
\Re : Transpose; Cant	5-96
Monad \Re	5-96
Dyad \Re	5-97

Transpositions that Retain All the Axes	5-98
Diagonal Slices	5-101
† ‡ : Raze; Take, Drop	5-105
Monad ‡	5-105
Raze of Empty Arrays	5-106
Raze Along Unit Axis	5-106
Dyad † and ‡	5-106
Take with Short Left Argument	5-108
Drop with Short Left Argument	5-109
Dropping More Elements than Exist	5-109
Over-Take and Padding	5-109
Take When the Right Argument Is Empty	5-110
Take and Drop Applied to Item α	5-110
Take and Drop Modified by the Rank Conjunction	5-111
‡ † : Grade up, Grade down	5-112
Monads ‡ and †	5-112
Grade is Not Tolerant	5-113
Dyads ‡ or † Grade Character Arrays	5-113
Collating Sequence with Tied Weights	5-114
Characters with Identical Weights	5-116
⍳ : Shape; Reshape	5-117
Monad ⍳	5-117
Dyad ⍳	5-118
⍷ : Member	5-120
Membership Modified by the Rank Conjunction	5-121
⍷ : Find, In	5-122
Dyad ⍷	5-122
⍷ : Iota; Count, Indexof	5-123
Monad ⍷	5-124
Default Rank of Monad ⍷	5-124
Dyad ⍷	5-124
Tolerant Comparison in Dyad ⍷	5-125
⍷[⍷] : Bracket Indexing	5-126
Shape of the Result Produced by Bracket Indexing	5-127
Keeping All Positions Along an Axis	5-127

Indexed Assignment	5-129
Effect of Indexed Assignment	5-130
Explicit Result of Indexed Assignment	5-131
6. Adverbs and Conjunctions	6-1
Precedence of Adverbs and Conjunctions	6-1
Valence of Adverbs and Conjunctions	6-2
Syntactic Class of the Arguments to an Adverb or Conjunction	6-2
Ambivalence of the Derived Verb	6-2
Consecutive Adverbs and Conjunctions	6-2
Example to Illustrate Order of Evaluation	6-3
Look-Ahead	6-4
Separating Side-by-Side Constants	6-4
Adverbs	6-6
v/w v/w n/w n/w : Reduction, Replicate, Compress	6-6
$v\backslash w$ $v\backslash w$ $n\backslash w$ $n\backslash w$: Scan, Expand	6-6
Summary of Forms	6-6
Monads Scan and Reduce	6-7
Effect of Order of Grouping on Scan and Reduce	6-7
Reduce When Argument Has One Cell or None	6-8
Some Examples of Reduce	6-10
Some Examples of Scan	6-10
The Derived Verbs Replicate and Expand	6-12
Replicate	6-12
Compress	6-13
Expand: Introducing "Fill" Cells	6-14
Derived Verbs Modified by Axis Bracket Notation	6-14
Conjunctions δ \circ $\circ\circ$	6-15

Grouping in the Discussion of Conjunctions	6-15
Conjunctions \cup \cap \vee with Verb Arguments	6-16
Under Requires a Known Inverse	6-16
Derived Verbs Produced by Composition	6-17
Default Rank of the Derived Verb	6-17
The Rank Conjunction $\vee^{\circ} \cap$	6-19
Argument Rank vs. Complementary Rank	6-20
Within Cells, the "Ordinary" Rank Applies	6-20
Default Rank Not Defined for Some Verbs	6-20
Examples of Rank	6-21
The Cut Conjunction $\cap^{\circ} \vee$	6-22
Types of Cuts	6-22
Cells Selected by Table	6-23
Cells Selected by Boolean Partition	6-24
Monadic Use of 1- and 2-Cuts	6-26
Shape of the Result Produced by Cut	6-26
Dot Conjunctions	6-26
Tie and Outer Product	6-27
Inner Product	6-29
Result Shape of Inner Product	6-29
Extending One Argument to Match the Other's Length	6-29
Inner Product and Matrix Product	6-30
Monadic Use: The Alternant	6-33
Non-Square Arguments	6-34

7. Verb Formation

Mechanisms for Defining and Editing Verbs

Representation of a User-Defined Verb

Canonical Form	7-3
Names in the Header	7-4
Headers for Monadic, Dyadic, and Ambivalent Verbs	7-4
Localization of Names	7-5

Using the V-Editor

Prompts in the V-Editor	7-6
Editing Commands	7-7
Interpolating Lines Between Existing Lines	7-7
Empty Lines	7-7
Synactically Invalid Lines	7-7
Box-drawing Characters	7-8
Editing Occurs in Real Time	7-8

Closing the Definition	7-8
Locking the Definition	7-8
Editing Can Prevent Resumption of Execution	7-8
Distinguishing Active, Pending, and Suspended Verbs	7-9
Damage to the Active Verb	7-10
Damage to a Pending Verb	7-10

8. Control of Execution.....8-1

Programming and Immediate Execution	8-1
Status of Work in Progress	8-2
Suspension Due to Error or Interrupt	8-3
Pending vs. Suspended Verbs	8-4
The Line Counter	8-4
Local Names at Each Level of the State Indicator	8-5
Dynamic Localization	8-6
Steps at the Start of Execution of a User-Defined Verb	8-7
Example of Argument and Result Passing	8-7
Multiple Copies of Arrays Share the Same Space	8-8
Value Returned by the Verb at Completion	8-9
Branch Controls the Sequence in Which Lines Are Executed	8-9
Form of a Branch Statement	8-9
Result and Effect of a Branch	8-10
Effect When Destination Is Zero or Out of Range	8-10
Effect When Destination Is Empty	8-10
Branch in Execute	8-11
Branch in a Line with Diamonds	8-11
Branch to Resume Suspended Execution	8-11
Resumption Following a Mid-line Halt	8-12
Naked Branch to Abandon Execution	8-12
Clearing the Entire State Indicator	8-12
Branch During Input	8-12
Calculating the Destination of a Branch	8-13
Conditional Branch	8-13
Conditional Execution of Statements on the Same Line	8-13
Multi-way Branch	8-13
Branch with Counter	8-14
Stop and Trace Controls	8-14
Effects of Stop	8-15
Effects of Trace	8-15
Effect of Editing on Trace or Display	8-16
Effect of Storing and Retrieving a Verb with Stop or Trace Set	8-16

9. Event Handling	9-1
Errors and Interrupts	9-1
Classifying Interrupts	9-1
Weak and Strong Interrupts	9-2
Signaled Errors	9-2
Trap, Action, and Recovery	9-3
Unreportable or Untrappable Events	9-3
Environment Condition Prohibits Suspension	9-4
Effect of 1 as the Value of $\square EC$	9-4
Values of $\square EC$	9-5
$\square EC=1$ in the SI Stack Prohibits Suspension	9-5
Response to an Event When Stop Is Prohibited	9-6
What Happens When an Event Occurs	9-7
Caution: Trapping Interrupts or Prohibiting Suspension	9-9
Caution: After Suspension, $\square trap$ Is Still Active	9-9
10. APL Component Files	10-1
Concepts of APL Component Files	10-1
Components	10-1
Indexed Access	10-1
File Size	10-1
File Reservation	10-2
File Primitives	10-2
Tying Links a File to the Verbs that Use It	10-2
Duration of a File Tie	10-2
File Access Controls	10-2
Summary of File Verbs	10-4
11. System Nouns and Verbs	11-1
Results of System Verbs	11-2
Alphabetical List of System Names	11-3
$\square ai$: Accounting Information	11-3

□append: Append Noun to Tied File	11-3
□appendr: Append Noun to Tied File with Result	11-3
□arbin: Arbitrary Input with Arbitrary Output	11-4
□arbout: Arbitrary Output	11-4
□av: Atomic Vector	11-4
□avail: File System Availability	11-4
□bounce: Terminate Task	11-4
□cr: Canonical Representation	11-5
□create: Create a File	11-5
□ct: Comparison Tolerance	11-6
Verbs Affected by □ct	11-6
□dl: Delay Execution	11-8
Behavior of Delay When Interrupted	11-8
□drop: Drop File Components	11-9
□ec: Environment Condition	11-10
□er: Event Report	11-11
□erase: Erase a Tied File	11-13
□ex: Expunge Objects	11-13
□fc: Format Control	11-14
□fd: Verb Definition	11-14

□fhold: Hold Tied Files	11-16
□fi: Input Format Conversion	11-16
Use of □fi with □vi	11-17
□fm: Function Monitor	11-17
Dyad □fm	11-17
Monad □fm	11-19
Storage Allocated to Monitoring Data	11-19
Monitoring a Recursive Definition	11-20
□fmt: Format Output	11-21
Format Phrases	11-21
Repetition Factors	11-23
Type and Shape of the Right Argument of □fmt	11-23
Shape of the Result of □fmt	11-23
Qualifiers and Decorators	11-23
Examples of □fmt	11-26
□fx: Fix a Definition	11-27
□hold: Hold Tied Files	11-27
□io: Index Origin	11-28
Verbs Affected by □io	11-29
□lc: Line Counter	11-29
□lib: File Library	11-30
□load: Load a Workspace	11-30
□qload: Load a Workspace Quietly	11-30
□lx: Latent Expression	11-31
□names: Names of Tied Files	11-31
□nc: Name Class of Identifiers	11-32

Onl: Name List	11-32
Onums: Tie Numbers of Tied Files	11-33
Opack: Build a Package	11-33
Opdef: Package Define	11-33
Oppdef: Protective Package Define	11-33
Protective Definition	11-34
Opex: Package Expunge	11-34
Opins: Package Insert	11-34
Oplock: Package Lock	11-35
Opnames: Package Names	11-35
Opnc: Package Name Class	11-35
Opp: Print Precision	11-36
Oppdef: Protective Package Define	11-36
Ops: Position and Spacing in Display	11-37
Opset: Package Select	11-38
Opval: Package Value	11-38
Opw: Page Width	11-39
Oqload: Load a Workspace Quietly	11-39
Ordac: Read File Access Table	11-39

Qrdci: Read File Component Information	11-39
Qread: Read Component of a Tied File	11-40
Qrename: Rename a Tied File	11-41
Qreplace: Replace Noun Stored in a Component	11-41
Qresize: Set File Size Limit	11-42
Qrl: Random Link	11-42
Qsignal: Terminate and Signal Event	11-43
Qsize: Size of Tied File	11-44
Qstac: Set File Access Table	11-45
Qstie: Share Tie	11-45
Qtie: Exclusive Tie	11-45
Qtrap: Event Trap Control	11-46
Qtrap Event Numbers Field	11-47
Qtrap Qualifier Field	11-47
Qtrap Action Field	11-47
Qtrap Recovery Expression	11-48
Action s : Stop	11-48
Action n : Next	11-48
Action i : Immediate	11-48
Action e : Execute	11-49
Action c : Cut Back and Execute	11-49
Action d : Do	11-49
Qts: Timestamp	11-50
Qui: User Load	11-50
Quntie: Untie Tied Files	11-51

□vi: Verification of Input Format	11-51
□wa: Work Area Available	11-51
□ws: Workspace Information	11-52

12. System Commands

)clear: Clear Active Workspace	12-2
Conditions in a Clear Workspace	12-2
)continue: Terminate APL Session for Restart	12-3
)copy: Copy Objects into Workspace	12-3
)pcopy: Protected Copy into Workspace	12-3
)drop: Delete a Workspace	12-3
)erase: Erase Global Objects	12-4
)fns: Display Verb Names	12-4
)group: Alter a Group	12-5
)grp: Display Group Member Names	12-5
)grps: Display Names of Groups	12-5
)lib: Display Saved Workspace Names	12-5
)load: Activate a Workspace	12-6
The)xload Variant	12-6
)off: Terminate APL Session	12-6
)pcopy: Protected Object Copy	12-6

)reset: Clear SI Stack	12-6
)save: Save Active Workspace	12-7
Workspace Locks	12-7
)sic : State Indicator Clear	12-7
)si: State Indicator	12-8
)sinI: State Indicator with Namelist	12-8
)siv: State Indicator with Namelist	12-8
)symbols: Set Symbol Table Size	12-9
)vars: Display Noun Names	12-10
)wsid: Set Workspace Name	12-10
)xload: Load Workspace without Autostart	12-10

13. Messages.....13-1

Sources of Messages and Trouble Reports	13-1
--	------

Trappable Errors and Interrupts	13-1
--	------

Form of an Error Message	13-2
How Much Has Been Executed	13-2

Error Messages By Event Number	13-3
System Nouns with Invalid Values	13-9

Interrupt Events	13-10
-------------------------------	-------

Figures

<i>Figure 1-1: Elementary examples to illustrate some aspects of APL.</i>	1-1
<i>Figure 2-1: Tree representation of $a \times b$.</i>	2-6
<i>Figure 2-2: Tree representation of $(a+b) \times (a-b)$.</i>	2-6
<i>Figure 2-3: Characters permitted in names and numeric constants.</i>	2-21
<i>Figure 2-4: Symbols in syntactic classes.</i>	2-22
<i>Figure 3-1: Alternative ways of partitioning a 2-by-3-by-4 array into cells.</i>	3-4
<i>Figure 3-2: Internal representation of APL characters.</i>	3-9
<i>Figure 3-3: A 2-by-3-by-4 array of boxes.</i>	3-11
<i>Figure 5-1: Default argument ranks of primitive verbs.</i>	5-3

1 Overview

This manual documents APL as provided in systems from Iverson Software Inc. This dialect of APL is based on Version 20 of SHARP APL.

Introduction by Example

This section shows what you would see on your screen after starting APL and entering a few simple lines. Type the APL symbols \leftarrow \times $+$ ρ by pressing the ALT key and typing p $-$ $=$ r .

```
2+3
5
prices←6 4 2.5 3
orders←3 1.5 0 2
costs←orders×prices
+/costs
30
(+/costs)←ρcosts
7.5
```

Figure 1-1: Elementary examples to illustrate some aspects of APL.

- *Interaction.* You enter the first input from the keyboard:

```
2+3
```

As soon as you press the *Enter* key, APL executes the sentence you have just entered and the result 5 appears.

- *Dialogue.* To show that it is ready for new input, APL moves the cursor from the left edge to six positions to the right. Now you can enter something else. The dialogue is clear because what you type is indented and what the computer replies is not.

- **Parts of speech.** The grammar of APL is described in terms like those used to describe natural language. In the example, you can see the principal parts of speech:

- **Nouns** are numbers (such as 2 or 3 1 0 2) or characters (such as 'abc'). To indicate that what you write is a character, or a set of characters, you place a quote mark (') at the beginning and another at the end, as you do in English.
- **Pronouns** are names arbitrarily assigned to nouns. In the example, *orders* is a pronoun that stands for the noun 3 1.5 0 2, and *costs* is a pronoun assigned to the result of multiplying *orders* by *prices*. A pronoun is thus equivalent to what mathematicians call a *variable*. It is variable in the sense that (like a pronoun in natural language) it does not have a fixed meaning, but can be associated with different nouns at different times.
- **Verbs** (such as + or ×) act upon nouns or pronouns.
- **Adverbs** (such as /) and **conjunctions** (such as ⋄) apply to verbs to produce related verbs. For example, in +/ the adverb / modifies + (addition) to produce a verb you might call "summation." The dot conjunction . produces a verb which performs inner product on matrices or tables.
- **Is** (or, as grammarians say, the *copula*) links a thing and some attribute. APL uses ← to link a pronoun and the name (or pronoun) assigned to it. A sentence such as

rate←1.6

may be read as "rate is 1.6."

- **Collective nouns.** A noun may be a single number or character or a collection of many numbers or many characters known by a single name. Because the members of such a collective noun are arranged rectangularly, a noun is said to be an *array*. Collective nouns include *lists* or *tables*, as well as higher-rank arrays. The simplest possible array has no rows or columns, and consists of a single item. APL allows direct use of a collection. That is, in many situations, an APL sentence is written the same way regardless of whether a noun in the sentence consists of a single item or many items.
- **No declarations.** Some programming languages require that you state in advance the type and shape of data to which a name will refer. In general, APL does not use declarations.
- **Display.** APL automatically displays the result of a calculation (unless you tell it do something else with the result). It is not necessary to

request display or to tell APL how to format it (although you may, when you want a different format).

- *User-defined verbs.* New verbs can be created and given arbitrary names. In other respects, they are used in the same way as other verbs.
- *Saved workspaces.* You can build on work done earlier by making use of saved workspaces.
- *Programs.* Programming is the creation of new verbs. In other languages, these may be called programs or functions or procedures. The APL system provides both a line editor and a full-screen editor to help you enter or revise definitions.
- *Nested definitions.* A verb may refer to other user-defined verbs in its definition. A verb can also refer to itself; a verb that does so is said to be *recursive*.
- *Reading and speaking.* Because of the similarities between the grammar of APL and the grammar of a natural language such as English, a well-written APL sentence may be read aloud with clarity. For example:

<code>prices←6 4 2 3</code>	"Prices are 6, 4, 2, and 3."
<code>-(⌈/prices),⌊/prices</code>	"Difference between the
<code>4</code>	maximum and minimum
	<code>prices."</code>
<code>+⌵odd←1+even←2×+⌵6⍱1</code>	"The cumulative sums
<code>1 4 9 16 25 36</code>	of odd, which is 1 less
	than even, which is
	twice the cumulative
	sums of 6 ones."

Arrays

With the exception of packages, every noun is an *array*. APL also provides a noun called a *package*.¹ An array is composed of any number of *items*, arranged along any number of *axes* or *dimensions*.

There is no special procedure for saying "This is an array," since every noun is automatically an array. An array that contains only one item and has no axes at all is just a particular case of an array, called a *scalar*.

¹A *package* is a special type of noun with some useful properties for treating disparate objects together. A package is not an array - its various members are identified by name rather than by position. Packages are identified in Chapter 3, "Nouns and Pronouns".

When a verb refers to a noun, it refers to the array *as a whole*. Depending on what the verb is and how it is used (and how it may be modified by adverbs), the verb either treats the entire array collectively, or considers the array to be a set of cells, so that the verb applies to each of the cells in *parallel fashion*.

Arrays are *homogeneous*. That is, all the items within an array must be of the same type. The type of item within an array determines the type of array.

An item – and thus an array – may be:

- *Numeric*. Numbers in APL may be Boolean, integer, real, or complex.
- *Character*. For example, 'x', 'cost'.
- *Box*. A box is a single item that contains an array *enclosed* within it. As long as the box remains closed, it can occupy a single position in an array, just as a single number or a single character can. Boxes permit data of differing types and irregularly shaped data to be stored in a regular rectangular framework.

Origins of APL

APL grew from proposals for a notation for the representation of algorithms put forward by Dr. Kenneth E. Iverson and published in his seminal work *A Programming Language*.² In 1966 the initial letters of the book's title were adopted as a name for the language.

Dr. Iverson's proposals extended existing conventions of arithmetic and algebra to embrace computation. He made extensive use of common mathematical symbols. In addition, he followed standard mathematical practice in assigning meanings to existing special symbols (for example, the Greek letters *iota*, *rho*, and *epsilon*) and in coining new but mnemonic symbols (for example, \mathbb{Q} for transpose).

Iverson's notation existed – and continues to exist – independently of computer systems to execute it. It provides a ready means of expression wherever people need to discuss formulas or procedures: in books, on blackboards, or even the backs of envelopes. Publications written in APL³ appeared before any attempt had been made to build an APL computer system. APL is used in several texts simply as a vehicle for describing a procedure to human readers. The attraction of the language is that it provides a rich set of convenient and powerful operations as primitives,

² New York: Wiley, 1962.

³ For example, Iverson, Sussenguth and Falkoff, "A Formal Description of System/360," *IBM Systems Journal*, vol. 3, *Special Issue*.

each denoted by a single symbol. Because of that, APL permits very concise statement of common procedures from business, finance, engineering, mathematics, and so on.

Development Related to Array Processing

APL borrowed from matrix algebra the idea that an operation may be defined on an array as a whole rather than on each of its elements separately. Because of this, many procedures that in other languages require indexes and loops can be written much more simply in APL. Several texts take advantage of this fact to present parallel discussion in matrix algebra (for continuity with the published literature, for example in economics or statistics) and in APL (for immediate execution at an APL device).³

Since so much of data processing involves the analysis of data arrays, the fact that APL operations apply directly to arrays often makes APL programs simpler and shorter than programs written in other languages. Because of its array orientation, APL requires much less iteration, looping, testing, and branching. APL lacks constructs that correspond to the DO, FOR, or WHILE instructions of some other languages.

Also because of its array orientation, APL is rich in verbs for the manipulation of arrays: shape, reshape, rotate, transpose, take or drop part of an array, compress, expand, replicate, and so on. Because these array operations are little described in conventional arithmetic, there are no established symbols for them; verbs dealing with array manipulation account for many of APL's coined symbols.

APL includes provision for *indexing*; that is, selecting individual items from within an array. However, APL programs often make less use of indexing than would be required in languages whose verbs are defined only on single items. Moreover, the APL interpreter is designed for efficient processing of verbs applied to an entire array, so that a program written to exploit the extensive array-handling powers of APL usually runs faster than a program defined iteratively for individual elements.

A number of recent additions to the language continue to develop the treatment of arrays. Foremost of these is the concept of *rank*, and the related ideas of *cell* and *frame*. Briefly, an array of data is considered to consist of *cells*. Each cell provides the data for a single case. For example, a single case might be a table, requiring two axes (rows and columns). The cells are arranged in a *frame*, which may itself have any number of axes. An operation is applied throughout the frame. It is applied automatically to each of the cells without the need to write loops, tests, or iterations. The concept of rank is pervasive in "A Dictionary of APL," and widely

³For example, *APL\360 with Statistical Applications*, by Keith W. Smith, Addison-Wesley, 1974.

mentioned in this manual,³ even though APL does not provide all of the uses of rank described in "A Dictionary of APL."

Another development in the language is the addition of *boxes*. A box is an item. It occupies a single point in an array, just as a number or a character occupies a single point. However, when you open the box, it may contain an array of any type or shape or size. Thus, the regular structure of an array may contain other arrays within it.⁴

Interpretive Basis for APL

APL is interpretive rather than compiled. That is, a program written in APL is stored in the machine in more or less the form in which it was written. The machine does not attempt to attach meaning to the words or symbols, or to assign space in which to store data, until a sentence is actually executed.

There are some costs in delaying interpretation until the moment of execution. There are also important benefits. The costs are minimized when programs make use of APL's power to deal with arrays, since a single symbol or expression may invoke a great deal of processing.

The great advantage of interpretation to the developer of a program, or to an informed user, is that it is so easy to make corrections or changes to the program as it goes along. Each time the program halts, whether in response to an error or to an interrupt signaled from the keyboard, you can display the values of intermediate results, look at or modify the program, and then resume work. It is even possible (although not necessarily a good idea) to start running a program before many of its parts are defined and fill them in as the need arises.

³ Examples of the uses of rank are given in R. Bernseddy, "An Introduction to Function Rank," *Association for Computing Machinery, APL Quote Quad*, vol. 13, no. 2, 1983.

⁴ In the APL literature, an array whose members are boxes has been variously called a *general array*, a *nested array*, an *enclosed array*, and an *array of arrays*.

2 Grammar

APL is an *imperative* language; its sentences do not make assertions or ask questions, but issue instructions. In natural language, the subject of an imperative sentence is not stated. Similarly, in APL sentences are addressed to an unidentified interpreter whose task is to carry them out.

APL Syntax

The APL system executes sentences written in the APL language. To interpret a sentence correctly, the interpreter must observe the language's grammatical rules. You, the human user of APL, need a similar understanding, both so you can interpret sentences you read and so you can write sentences that, when executed, do what you intend. This chapter describes APL's grammar.

Syntactic Classes

The *syntax* of a language is the body of rules that govern the way sentences are assembled. A sentence in APL is put together from names and symbols. They fall into the following syntactic classes:

Noun A noun is made up of numbers, characters, or boxes arranged in an *array*. A noun may also be a package.

Constant A noun whose value occurs directly in a sentence (for example, the numbers 1 2.2 3 or the characters 'abc').

Pronoun An arbitrary name that has been assigned to a noun, so that one may refer to the noun by using its name. It is called a *pronoun* because the name is an arbitrary substitute that is understood to refer to the value most recently assigned to it. In mathematics, a pronoun is commonly called a *variable* because the value to which it refers may vary.

Fundamentally, the aim of data processing is to transform the nouns (data) that you have to some other nouns that you find more useful, more interesting, or more convenient. Both the input and the output are – by and large – nouns.

Verb A verb¹ specifies an action to be taken. In general, a verb applies to a noun or a pair of nouns and produces a noun as its result. Defining verbs is thus central to data processing: verbs transform the nouns you have to the nouns you would rather have.

The noun to which a verb applies in a particular sentence is called the verb's *argument*. In APL, a verb may take no arguments, one argument noun (to its right) or two argument nouns (one on either side).

Primitive verb A *primitive verb* is one defined in the APL language. It is "built in" to the APL system, so that its meaning is always known to the interpreter. Each primitive verb is denoted by a single symbol such as +. The primitive verbs are described individually in Chapter 5, "Verbs".

System verbs The interpreter also recognizes a set of *system verbs* that denote extensions to the APL language for which no symbol has been designated. Each has a *distinguished name* consisting of the symbol □ followed by certain letters. They are described individually in Chapter 11, "System Nouns and Verbs".

User-defined verb A *user-defined verb* has an arbitrary name rather than a symbol. Its definition consists of a *header* that declares its name and establishes internal names for its arguments and result, and a *body* consisting of lines containing APL sentences that describe how the verb arrives at its result. You use a defined verb in much the same way as a primitive verb; like a primitive verb, it may take either one or two arguments.¹ Creating a user-defined verb in effect extends the APL language. Once you have defined a new verb, you can execute it or make use of it in the definitions of other verbs. Programming is the art of writing definitions for user-defined verbs.

Adverb An *adverb* modifies the action of a verb to produce a new verb. Each adverb is denoted by a symbol. The adverbs are described individually in Chapter 6, "Adverbs and Conjunctions".

Conjunction A *conjunction* modifies the action of a pair of verbs, or a verb and a noun, to produce a new verb. Each conjunction

¹ Also called a *function* or a *program*.

² It is also possible to define a verb that takes no arguments, and which therefore behaves like a noun; its value is the result returned by executing the verb.

is denoted by a symbol. The conjunctions are described individually in Chapter 6, "Adverbs and Conjunctions".

Copula Like "is" in English, the copula \leftarrow links a name to the noun being named. Also called *assignment*.

Branch The *branch arrow* \rightarrow alters the sequence in which the lines of a user-defined verb are executed. Used from the keyboard or in the recovery expression of `⌈trap`, it may also restart execution of a verb whose execution has been suspended.

Punctuation Instructions written in APL are grouped into phrases, sentences, and paragraphs, just as they are in a natural language. Parentheses are the principal punctuation in APL; as in natural language and in conventional mathematics, they set off a phrase that must be treated as a unit. APL also uses certain other delimiters.

Evaluation

To evaluate a sentence is to replace each of its adverbs or conjunctions and their arguments with the resulting verb, and then to replace each verb and its arguments with the resulting noun. You end up with a noun (unless the sentence has no result).

The APL interpreter either displays the result (when you did not say what else you wanted done with it) or passes it on to be stored or to be processed by some other verb.

Order of Execution

When a sentence contains just one verb and its arguments, all that is required is to execute the verb. When a sentence contains several verbs, or both verbs and adverbs, you have to have rules to decide what applies to what. From them, you can deduce the order in which to evaluate the various verbs.

You may read an APL sentence from left to right. Each verb (including the derived verbs you get by evaluating an adverb or conjunction) applies to the part of the sentence to its left and the part of the sentence to its right. For example, in the sentence

$$a \div b + c \div d$$

the first division takes a as its left argument, and $b + c \div d$ as its right argument. Within the expression $b + c \div d$, the divisor of b is $c \div d$. Thus:

$$a \div b + c \div d \iff a \div (b + (c \div d))$$

Because you are reading from left to right, this arrangement is not symmetric. There is at most one noun to the left, but all the rest of the sentence to the right. Another way to say the same thing is: A verb takes as its arguments the noun immediately to its left but the entire phrase to the right. Some authors express that by saying a verb has *short scope* on the left and *long scope* on the right.

Ruthlessly Consistent Order of Execution

APL's rule for order of execution is applied equally to all verbs, both primitive and user defined. This consistency makes an APL sentence easy to understand.

Nevertheless, the very consistency may surprise you. That is because APL does *not* make exceptions for certain common verbs that in ordinary algebra or arithmetic are given higher precedence than other verbs. For example, the expression

$$a+b-c*d$$

is executed in exactly the same order as $a+b*(c*d)$ or $a+b+c+d$ (just mentioned). That is, the $*$ takes as its right argument the expression $b-c*d$, and $-$ takes as its argument the expression $c*d$.³

Conventional languages use complicated orders of execution, yet are similar to APL when it comes to assignment. Common statements such as $x=b*c$ are executed right to left – the multiplication is performed first, followed by the assignment. APL is simpler than other languages in that the right to left execution order is preserved throughout the language.

Infix Notation

In APL, as in arithmetic, a verb appears *between* its arguments. That is, the verb is an *infix*.⁴

When a verb has only one argument, the argument is to the right of the verb.

Ambivalence

Valence is the number of things with which something can combine. In APL, the same verb can be used with two arguments (one on either side) and also with just one argument, on the right. Since the same verb can be used either with one argument or with two, verbs are said to be *ambivalent*.

³ In conventional algebra, the expression would be executed as if it were written $(a+b)-(c*d)$.

⁴ In languages such as C or LISP, primitive verbs are infixes; user-defined verbs are prefixes; in PostScript, all verbs are postfixes.

For example, the symbol $-$ appears twice in the following sentence:

$$-a-b$$

The first $-$ denotes "negation": a quantity is to have its sign reversed. The quantity to be negated is the difference between a and b . The second $-$ is used with two arguments and means "subtraction."

As this example shows, the practice of using the same symbol with just one argument, or with arguments on both sides, is already familiar from arithmetic.

Niladic, Monadic, and Dyadic Use

When a verb is used with arguments on both sides, it is said to be a *dyadic* use of the verb. Dyadic means "dealing with two arguments."

When a verb is used with only one argument, it is said to be a *monadic* use of the verb.

When a verb is used with no argument, it is said to be a *niladic* use of the verb. Verbs that are niladic can only be used that way - monadic or dyadic uses are forbidden.

The phrase "dyad +" refers to the verb + when it is used dyadically. The phrase "monad +" refers to the verb + when it is used monadically.

Grouping

As in natural language, parentheses surround an expression that is to be treated as a whole. When you evaluate a sentence that contains parentheses, you have to evaluate what is *inside* the parentheses before you can apply to it a verb that is *outside*. For example, the expression

$$(a+b) \times (a-b)$$

indicates that the arguments of the verb \times are the entire expression $a+b$ and the entire expression $a-b$. Thus you have to evaluate both $a+b$ and $a-b$ before you can start to evaluate \times .

Parentheses are redundant when they have no effect; they have no effect when the order of evaluation they impose is what the system would do anyway without them. Since in APL a verb applies to the entire expression to the right of it, it is never necessary (but not harmful) to put parentheses around a verb's *right* argument. You get the same result from

$$(a+b) \times a-b$$

as from

$$(a+b) \times (a-b)$$

In APL, the expression inside a set of parentheses must evaluate to a noun.

Tree Structure of a Sentence

The structure of a sentence can be represented by a tree. For a sentence with a single verb, you depict the verb as the root of the tree and its arguments as the branches.

Figure 2-1: Tree representation of $a \times b$.

Where the argument is in parentheses, draw a similar tree to represent the expression inside the parentheses.

Figure 2-2: Tree representation of $(a+b) \times (a-b)$.

For a sentence confined to verbs and nouns, and which refrains from re-defining the syntactic class of its names in mid-sentence, the tree can be constructed by the following (recursive) procedure:⁵

- Remove redundant parentheses surrounding the sentence (if any).
- If there is no verb, use the remaining noun. EXIT.
- If there is a verb, connect the root verb to its arguments, as follows:
 - The root verb is the first verb (scanning from left to right) that is not inside parentheses.
 - Its left argument is the part of the sentence to the left of it. Its right argument is the part of the sentence to the right of it.
- Apply the same rule to each of the arguments.

Left-to-Right and Leaf-to-Root

When the interpreter evaluates a verb, it has to know the values of the verb's arguments. But a verb applies to the *entire expression* to its right. So the interpreter has to find the value of the entire expression to the right before it can evaluate a verb. (That is true for any interpreter, human or machine: you cannot evaluate the root verb until you have established values for the leaves.)

The fact that APL is read from left to right requires the interpreter, when it executes a sentence containing several clauses, to evaluate the subordinate expressions (to the right) *before* it can interpret the main one (at the left). This is sometimes called the "right-to-left rule."⁶ It is perhaps better called "leaf-to-root" execution. Once you remove any redundant parentheses, *the root verb of an APL sentence is the first verb not enclosed in parentheses.*

Precedence of Verbs, Adverbs, and Conjunctions

The precedence rules of a language determine whether some verbs are evaluated ahead of others regardless of their position in the sentence. APL has only one rule of precedence:

- *An adverb or conjunction has higher precedence than a verb.*

This is because an adverb or conjunction modifies a verb, and you cannot execute the verb appropriately until you know how it has been modified.

Among themselves, all verbs have equal precedence; among themselves, all adverbs and conjunctions have equal precedence.

⁵ A listing of APL programs to produce trees in this fashion may be found in Berry et al., *APL and Insight*, paper presented to Colloque APL, Paris, 1971; reprinted by APL Press, 1974.

⁶ That name makes it sound somehow backwards, or somehow different from ordinary mathematics. In fact this is exactly the standard rule in mathematics.

- No verb has higher precedence than any other verb. That includes both primitive verbs and user-defined verbs.
- No adverb or conjunction has higher precedence than any other adverb or conjunction.

Because all verbs have equal precedence, the *only* determinants of order of execution are parentheses (in the usual way) and position in the sentence.

Conventional algebra also gives equal precedence to arbitrary functions. However, it has special rules for a few common functions. It gives exponentiation higher precedence than multiplication or division, and multiplication or division higher precedence than addition or subtraction.⁷ APL does *not* retain these precedence exceptions and is therefore easier to read and use than C-like languages.

Precedence in a Sentence with Adverbs or Conjunctions

An adverb takes as its argument the noun or verb that it follows.

A conjunction takes as its arguments the verbs (or the verb and noun) on either side of it.

Because adverbs and conjunctions have higher precedence than verbs, when (while reading through a sentence) you come to something that is modified by an adverb or conjunction, you evaluate the adverb or conjunction at once and replace it (and its arguments) by the resulting derived verb. For example, in the sentence

$$(a+b) \times^{\circ}(1,r) -(c+d)$$

the root verb is *times-rank-1,r*. Reading left to right, the quantity $(a+b)$ is to be multiplied. But \times is modified by the rank conjunction $^{\circ}$, so you have to evaluate the rank conjunction before you can do anything about the multiplication. The conjunction's arguments are the verb \times on the left and the noun $(1,r)$ on the right.

In order to evaluate $^{\circ}$, you have to evaluate its argument $(1,r)$. That done, you establish that the root verb is *times-rank-1,r*. Its right argument is:

$$-(c+d)$$

Notice that although the right end of the sentence contains the characters

⁷ The precedence rules of conventional algebra are reflected in its typographical conventions. The higher-precedence functions are conventionally denoted by juxtaposition (for instance, to indicate multiplication) or by a combination of juxtaposition and super- or sub-scripting (for instance, to indicate exponentiation or indexing). However, when computer programmers abandoned one-letter names, they had to abandon juxtaposition too. To simplify work from computers, APL and most other systems have *linearized* their input, and thus abandoned subscripts and superscripts. Languages such as Fortran and BASIC have retained the conventional precedence even though they lack the typographical conventions that in mathematics help express precedence.

$$(1,r)-(c+d)$$

$(c+d)$ is *not* subtracted from $(1,r)$. The precedence rule means that $(1,r)$ is the argument of the conjunction $\bar{\vee}$ and gets evaluated before the $-$ is performed.

Notice too that although a verb rarely requires parentheses around its right argument, a conjunction may indeed require them. In the foregoing example, omitting the parentheses around $1,r$

$$(a+b) \times \bar{\vee} 1,r-(c+d)$$

makes 1 the argument of the rank conjunction $\bar{\vee}$. The sentence then reads

the quantity $(a+b)$ times-rank-1 the quantity $,r-(c+d)$

which is not the same thing at all.

Other Mechanisms of Grouping

Although parentheses are the principal mechanism for grouping within a sentence, there are others that affect both execution within a sentence and the overall grouping of lines within a definition. They are discussed next.

Brackets⁸ are anomalous in APL. So are semicolons. Both date back to the earliest APL implementations. Both are obsolescent. That is, as the language develops, other more consistent mechanisms become available for tasks where brackets or semicolons were formerly indispensable. However, for the sake of consistency with old programs, the old meanings of $[]$ and $;$ are retained, even though need for them has vanished in newer dialects of APL, such as J.⁹

Brackets Group in the Same Way as Parentheses

The square brackets $[]$ serve both to group the expression inside (in much the same way as parentheses) and also to modify whatever is to the left of the bracketed expression. For example, in an expression such as

$$x[a+b]$$

the value found by evaluating $a+b$ is used to select particular members of the list x . The selection index is the result of the entire expression within the brackets.

⁸That is, the square brackets $[]$, in contrast to parentheses $()$, which are curved.

⁹J is a new dialect of APL, available as `sharvware`. J has removed the anomalous features of traditional APL. It also uses the ASCII character set instead of the APL character set and so is easy to use in conjunction with a wide range of hardware and software. J is described in "APL\J", APL90 Conference Proceedings, *APL Quote Quad*, vol. 20, no. 4, 1990.

Brackets are used to denote the verb *selection by indexing* (See "Bracket Indexing" in Chapter 5, "Verbs") and certain cases of the rank conjunction (described in Chapter 6, "Adverbs and Conjunctions").

Semicolon Is a Separator

The semicolon ; is used as a separator. There are two contexts in which it may be used:

- inside brackets used for indexing an array of two or more axes
- separating expressions in side-by-side output.

Semicolons inside brackets. Inside brackets, semicolons separate the expressions that specify positions along the various axes of an array. Thus one semicolon is required for an array that has two axes, two semicolons for an array that has three axes, and so on. Each of the expressions thus separated needs no other delimiter; in particular, it never needs to be enclosed in parentheses.

As long as brackets are used for indexing, semicolons appear to be a necessary adjunct to them. The direction of evolution in APL is to provide superior alternatives for bracket-semicolon indexing without actually immediately ceasing to support it.

Semicolons on mixed output. Anywhere else, semicolons separate successive sentences for side-by-side output to a terminal. For example, the sentence

```
'f(x) when i=';i;': ';table←(i-24) f x
```

sets the value of *i* to 24, and evaluates *i f x* and stores it as *table*. Then it displays the message

```
f(x) when i=24;
```

with the value of *table* to the right of it. This use of semicolon was formerly called *mixed output* because (since the various arrays that are displayed are produced by separate sentences) there is no need for them to be of the same type or shape. In modern APL, the same effect can be produced in a more consistent manner by the verb \Rightarrow (*link*). The direction of evolution is to discard semicolons in mixed output. They are not mentioned in the ISO standard and have been dropped from several APL systems, although not (at this point) from APL.

Mixed output with semicolons is permitted *only* at the root level of the sentence. A set of sentences separated by one or more semicolons may *not* be assigned a name and may *not* be used as the argument of any verb. For example,

`x←(a;b)`

is rejected as a *syntax error*, while

`x←a;b`

has the same effect as

`x←a
a;b`

A set of phrases separated by semicolons may be enclosed in parentheses *only* when the parentheses surround the entire sentence (and are therefore redundant). For example, the outer parentheses in the following are permissible but pointless:

`('a=';a;' b=';b;' a foo b=';a foo b)`

Other Punctuation

No other punctuation affects the interpretation of an APL sentence. The symbols

`:` (colon)

`⋄` (diamond)

`⌞` (lamp)

delimit parts of a *line*, but do not occur within a sentence except as they may be included in a character constant. (See "Scanning the Line for Quotes and Comments" and "Dividing the Line Into Sentences," later in this chapter.)

The colon occurs only to mark a label on a line in a user-defined verb and is not part of an APL sentence.

Similarly, the quote mark ' delimits a character constant within a sentence. However, as will be explained in the discussion of "Analysis of an Input Line", you have to resolve the use of quotes for the entire line before you can break it into sentences.

Thus, apart from the anomalous use of brackets and semicolon, grouping with parentheses is the only form of punctuation within an APL sentence.

Colon and Label

A label is a name assigned to a line within the definition of a defined verb. (See the discussion of labels in the section on "Localization of Names" in Chapter 7, "Verb Formation".)

The colon `:` serves to identify a label. A label is a name formed following the same lexical rules as for names of nouns or verbs. If a line is labeled,

the line must begin with the label, followed immediately by a colon. That is the only use of the colon. Since there may be at most one label on a line, there may be at most one colon.

Note that a label is attached to a line, not to a sentence. Thus, a line containing several sentences separated by diamonds may nevertheless contain only one label, and the label must appear first on the line.

Lamp and Comment

The lamp `*` marks the start of a *comment*, which is a portion of a line that contains text intended for the illumination of the human reader but not for execution by the APL interpreter. As it scans a line from left to right, when the interpreter reaches a `*` (other than one embedded within quotes) it ignores the `*` and everything to the right of the `*` on that line.

Note that a comment is part of a *line* rather than part of a *sentence*. When several sentences appear on the same line (separated by diamonds) each sentence may not have its own comment, since the first comment causes the interpreter to disregard the remaining characters on that line.

Since `*` ensures that the remainder of the line will not be executed, it does not matter whether the comment contains unmatched quotes, parentheses, brackets, or additional comment symbols. Nor does anything written in the comment affect the V-editor, which might otherwise respond to bracketed line numbers or to the symbols `⍷` or `⍶`.

Arrays

In general, a noun is an *array*,¹⁰ composed of any number of *items*, arranged along any number of *axes* or *dimensions*.¹¹

There is no special procedure for saying "This is an array," since every noun is by default an array. An array that contains only one item and has no axes at all is just a particular case of "array," sometimes called a scalar.

When a verb refers to an array, it refers to the array as a *whole*. Depending on what the verb is and how it is used (and how it may be modified by adverbs), the verb either treats the entire array collectively or considers the array to be a set of cells to which the verb applies in *parallel fashion*.

¹⁰ The only exception is a *package*, a noun whose various members are identified by name rather than by position in an array structure.

¹¹ APL limits an array to a maximum of 63 axes.

Types of Nouns

An APL array may be of one of three types. All the items within an array must be of the same type. The three types are:

- numeric
- character
- box.

A box is a single item that is an encoding of an array; the array is said to be *enclosed* within it.

No Declarations

There is no provision in APL to declare in advance the type, shape, or size of a noun. The APL interpreter simply notices what each noun's type and shape happen to be and allocates it space *as required*. It chooses various internal forms for the storage of numbers but converts between them automatically. Which internal type the system uses to store numeric data should concern you only insofar as it affects the amount of space that a stored array occupies, or as it affects the performance of primitive operations on that data.

The name assigned to a noun may be reused at will and may be assigned to a noun of different type or shape. Thus it is acceptable to say `x←6` in one sentence and later say `x←'Friday'`.

Input Modes

The possible modes of interaction at a terminal are:

Immediate execution This is the default.

When the first non-blank character is `)` (right parenthesis), the line is interpreted as a system command. See Chapter 12, "System Commands". When the first non-blank character is `⋄`, the line is interpreted as a call to the `⋄`-editor. See Chapter 7, "Verb Formation".

Character input In response to the symbol `⋄`, the next line you enter is interpreted as character data and is returned as the value of the symbol `⋄`. See Chapter 3, "Nouns and Pronouns".

Evaluated input In response to the symbol `⋄`, the system displays the symbols `⋄`: on a new line at the left margin,

and then moves to the next line and indents by six blanks.

The next line you type is treated as a line of APL to be executed. Its result is returned as the value of \square . You can write any APL line that would be acceptable in immediate execution mode, including a system command; but you may *not* invoke the ∇ -editor and you may not branch to a different line. (However, \rightarrow alone to abort execution – the so-called “naked branch” – is acceptable and aborts the entire sequence that called for \square -input. The input request can also be interrupted by entering an *input interrupt*. See Chapter 8, “Control of Execution” and Chapter 3, “Nouns and Pronouns” for a discussion of both topics.)

Editor input Once you have invoked the ∇ -editor, the next line you type is interpreted in the context of the editor. In general, the editor prompts by displaying a line number in brackets. (See Chapter 7, “Verb Formation”.)

Analysis of an Input Line

The syntactic rules within a sentence are quite simple. Entries that you type from the keyboard are executed a *line* at a time. Interpretation does not start until you signal that the line is complete by pressing the *Enter* or *Return* key, hereafter called *newline*. Similarly, the interpreter executes the definition of a user-defined verb a line at a time. It takes a little more analysis to process an entire line because the line may contain a label or a comment and may be divided into separate sentences by the *diamond* sentence separator. And any of these may occur inside quotes, where they do not count, so the location of quotes and comments must be analyzed before anything else.

Preliminary Checks for \rangle and ∇

A line entered from the keyboard may be a *system command*. When the first non-blank character in a line is \rangle (the right parenthesis), APL treats the entire line as a system command (and gives it no further consideration as APL sentences).

A line entered from the keyboard may invoke the ∇ -editor. When the first non-blank character in a line is ∇ (*def*), APL treats the entire line as an

invocation of the V-editor (and gives it no further consideration as APL sentences).

Neither a system command nor a call to the V-editor may be part of a user-defined verb.

A line may consist of one or more sentences separated by ♦, the *diamond*. However, a diamond that is part of a character constant or a comment does not act as a separator.

Scanning the Line for Quotes and Comments

Two symbols require special attention early in the analysis of a line. They are the *quote* symbol ' and the *comment* symbol *. Their meanings are as follows:

- ' ' *Quotes.* A character constant is delimited by the symbol ' before it and another ' following it. All the characters between the quotes (but not the delimiting quotes themselves) are part of the constant. Within a quotation, two consecutive quotes denote the quote character itself.
- * *Comment.* The first occurrence of * that is *not* part of a character constant (and thus is *not* enclosed within quotes) indicates the start of a comment. All the rest of the line is the comment and has no effect on the interpretation of the line.

Since the character ♦ between quotes or to the right of * is simply a character and has no power as a delimiter, you cannot divide a line into sentences until you have scanned for quotes and comments. Proceed as follows:

- Note the locations of the symbols ' and *.
- Scan left-to-right for the first * that has an even number of quotes to the left of it. (Zero is an even number.) That jump and everything to the right of it is a comment. Discard the comment. It is not an executable part of the line.
- Count the number of quotes that remain. In a line that has an odd number of quotes, it is impossible to tell which characters are supposed to be inside and which outside the quotation. Give up. Reject the entire line as a *syntax error*.
- Scanning from left to right, mark each character constant. A character constant starts with the first use of a quote and runs until a closing quote. At a position in the sentence where a character constant has started but not yet ended, two consecutive quotes denote the quote character itself and do *not* serve as a closing quote. For example, the sentence

`a←'I can't',b`

contains a single character constant composed of the seven characters

`I can't`

- Any `◊` that is *not* inside quotes is a sentence separator.

Dividing the Line into Sentences

Each line commonly contains one sentence. Frequently, *sentence* and *line* are equivalent.¹³ When a line contains more than one sentence, the successive sentences are separated by the symbol `◊` (*diamond*).

The sentences in a line are executed in order from left to right. When one of the sentences is a *branch*, it may cause control to go immediately to the destination of the branch; if it does so, sentences further to the right are not executed.

A sentence that contains no characters, or only blanks, is said to be empty. It does nothing, but it is not an error.

Types of Sentences

APL has three types of sentences:

Branch The first non-blank character is `→`. It causes control to pass to the line identified by the value to the right of the arrow. Branching is discussed in Chapter 8, "Control of Execution".

Assignment The root of the sentence is the copula `←`. The noun resulting from evaluating the expression to the right of the arrow is assigned the name to the left of the arrow. There is no display.

Everything else The result of the root verb is displayed.¹⁴

Dividing a Sentence Into Words

A *word* is one or more characters that, in the interpretation of a sentence, can be treated as a unit. For example, each of the APL symbols for a primitive verb or adverb is a single word, since each stands alone. However, a *name* is just one word, regardless of the number of characters required to spell

¹³ "A Dictionary of APL" does not include diamond and assumes that *line* and *sentence* are always equivalent.

¹⁴ If it has a result. A few primitives return no result; a user-defined verb may be defined so that it has no result.

it, just as a number is a single word, regardless of the number of digits required to represent it.

APL uses many symbols and several punctuation marks. Each of these symbols is a word by itself.¹⁴ When you see one of those symbols, you can treat that character as a word.¹⁵ You know that it cannot be part of some other word.

Multi-character Words

Words of more than one character occur in three classes:

Name The name assigned to a user-defined noun or verb may contain up to 77 characters. (The characters permissible in a name are described later in this chapter.)

Numeric constant Several digits, and also the decimal point, the negative sign, and the letters *e* and *j*, may occur in the spelling of a single number. The macron $\bar{}$ is the negative sign; note that this "high minus" is *not* the same thing as the subtraction sign. A list of several numbers separated by blanks forms a single word.

Character constant A character constant, as described earlier, is delimited by ' at either end. Between the delimiting quotes, the constant may contain any non-control characters (subject to the limitations of the device to enter or display them).

Blanks

A blank cannot occur as part of a name or part of the representation of a single number. Blanks serve to separate two characters that might otherwise appear to be part of the same number or the same name. Blanks are not otherwise significant, except in character constants.

Blanks are required to separate two consecutive names (for example, the name of a verb and its argument or the names of two user-defined verbs) or a name and number.¹⁶

¹⁴ For this purpose, we consider not only symbols (such as + - * /) to be words, but also any of the punctuation marks (such as () [] etc.), even though in English, the category "word" does not usually include punctuation.

¹⁵ Except, of course, when it is inside a quote or comment.

¹⁶ In the APL system, if (while writing the definition of a verb) you put extra blanks between words (perhaps intending to give a more pleasing visual effect), the extra blanks are not retained in the definition. When the interpreter "fixes" the definition (for example, by using the `⎕FX` verb), the definition is converted to an internal form that does not need delimiters. When you subsequently display the verb's definition, the interpreter regenerates the display from the internal form, but it has no record of the redundant blanks.

Scanning Strategy for Locating Words

Each of the APL primitives is represented by a single symbol and is a single word. Because it is a single word, it needs no delimiter beside it. In scanning a line of APL, the following algorithm exploits that fact. The strategy is:

- Locate the left-most character that may be the start of a multi-character word. You have found the start of a possible word when:
 - the present character could be the start of a name or a constant
 - the preceding character could not be part of a name or constant.
- Assume that the name or constant continues until you reach a character that could not be part of it. Then you know that the preceding character was the end of the name or constant.

Numeric Constants

A sequence of characters may spell a numeric constant. A numeric constant may represent just one number or several numbers separated by blanks. For example, the expression

$$b+3.1 \times a$$

has a numeric constant consisting of just one number (3.1), while the expression

$$b+3.1 \text{ } ^{-}2 \times a$$

contains a single numeric constant consisting of the two numbers 3.1 and $^{-}2$.

Blanks that are surrounded by numbers delimit the numbers from each other but do not mark the end of a numeric constant. (For example, the blank between the 1 and the $^{-}$.)

In a numeric constant, the first character of the first number must follow a character that could not be part of a constant (or must be at the start of the sentence). In the preceding example, the numeric constant starts after the symbol +.

Scanning from left to right within the same numeric constant, the first character of each subsequent number must have a blank in front of it. The blank in front of $^{-}2$ is necessary to separate $^{-}2$ from 3.1; however 3.1 $^{-}2$ is a single word.

Complex and Exponential Number Formats

A number may be real or complex. A complex number is written as two real numbers separated by the letter *j*; for example:

3.1j5

Thus the letter *j* may occur in a number, but not more than once, and only with a real number both before and after it.

A real number may be written in either of two ways: decimal or exponential. The exponential form consists of a decimal number, the letter *e*, and an integer; for example:

3.1e⁻⁹

Thus the letter *e* may occur in a number, but not more than once (or more than once in each part of a complex number), and only with a real number in front of it and an integer after it.

A number must start with one of the characters 0 through 9 or the negative sign ⁻ or the decimal point. After a number's first character, subsequent characters may be any of the characters 0 through 9 or the decimal point. However, a number cannot contain more than one decimal point if real, or one in the real part and one in the imaginary part if complex.

A number may not contain a comma; comma is a stand-alone symbol and thus a word in itself.

Dot is a decimal point when it occurs next to a digit, but a conjunction otherwise.

List Constants

A constant may be a list of several numbers or characters. The general rule is as follows: while scanning a line from left to right, upon first encountering the first character of a number, assume that it may be the start of a numeric list. Scan rightward at two levels:

- Look for a blank or a character that could not be part of a number.¹⁷ Since it could not be part of a number, you know that the preceding character is the last of this number.
- Look for a character that could not be part of any number. It terminates this list of numbers.

¹⁷As you scan, you have to revise the list of characters that could be part of a number. For example, when you have only seen numerals, the decimal point is an eligible character. However, once you have observed one decimal point in a number, a decimal point is no longer eligible to continue the same number.

Similarly, a character constant forms a single word. However, the two-level scan is not necessary because (unlike a numeric list) a character constant has an explicit delimiter, the quote mark.

After detecting the opening `'`, assume that it may be the start of a character list. Scan rightward looking for a closing quote.¹⁴

A character list is a single word.¹⁵ Anything adjacent to a character list cannot be in the same word. Hence a character constant does *not* need any additional delimiter in front of the opening quote or after the closing quote.

Names

A sequence of characters may spell a name. The first character of a name must be located at the beginning of the sentence or after a character that could not be part of a name.

The first character of a name must be a member of the set considered *alphabetic* (see below) or the symbol quad (`⎕`). Names that start with `⎕` are called *distinguished names*. The only valid distinguished names are those recognized by the APL system; that is, although you are free to coin arbitrary names that start with something other than `⎕`, you are not allowed to coin arbitrary distinguished names.

The "alphabetic characters" are those permitted as the first character in user-defined names. The set accepted by APL contains the 52 characters used in English words (without diacritical marks):¹⁶

```
abcdefghijklmnopqrstuvwxyz
ABCDEFGHIJKLMNOPQRSTUVWXYZ
```

APL's set of alphabetic characters also includes the characters `Δ` and `Δ;`; they are permitted in names in the same way as other alphabetic characters. The characters `α` and `ω` may be used as names but may not form part of a longer name. By convention, they are used as the names for the left and right arguments of user-defined verbs.

Names are not permitted to start with the characters `sΔ` or `cΔ`. These prefixes are reserved for control over trace and stop capabilities.

¹⁴ This requires looking ahead for two characters, since once a quote has started, the sequence `''` denotes a single quote character rather than the end of the quotation.

¹⁵ Note that *word* is here used in a special sense; the list `'hot dog'` is for this purpose one word, even though the blank in the middle seems that in natural language we would treat it as two.

¹⁶ "A Dictionary of APL" describes the characters used in names as those in the system's "native alphabet," which in principle permits a system to recognize whatever characters are employed in a particular national alphabet. APL nevertheless confines itself to the 26 Latin-derived characters without diacritical embellishments. You can write characters such as `Å` and `Ö` in text but not in the names of APL objects.

A name continues until (scanning from left to right) you reach a character that could not be part of it. After its first character, a name may contain any letter of the alphabetic set or a digit. A digit is one of the characters 0 through 9. A name may not contain a blank. A name may not contain more than 77 characters.²¹ Figure 2-3 provides a summary of characters permitted in names and numeric constants.

Permitted in a <i>Name</i>	Permitted in a <i>Numeric Constant</i>
a ... z	0123456789
A ... Z	- . e j
Δ Δ	
0 ... 9 (not at start)	
(Also α or ω alone)	

Figure 2-3: Characters permitted in names and numeric constants.

Assigning Words in a Sentence to Syntactic Classes

To execute a sentence, you have to know what applies to what. Such analysis is called *parsing*. Identifying which verbs take which arguments in effect defines the order in which the verbs must be executed. Parsing requires identifying the syntactic class to which each word belongs. The syntactic class of a symbol can be determined from the chart shown in Figure 2-4. The syntactic class of a name is arbitrary; the interpreter determines that by consulting the name's entry in the workspace's symbol table.

²¹ APL applies stricter rules to the names of files and workspaces.

Punctuation	Branch	Copula	Verb	Adverb	Conjunction	Noun
() [] : : : : :	→	+	+ × − ÷ ∗ ∘ ⌈ ⌊ ⌠ ⌡ ⌢ ⌣ < ▢ = ≥ > ≠ ∧ ∨ ⋈ ∩ ∪ ∩ ↑ ↓ ∼ ∘ ? ⊛ ⊞ ⊙ ⊛ ⊛ , ⌈ ⌊ ⌠ ⌡ ⊞ ⊞ ⊞ ⊞ ⌈ ⌊ ⌠ ⌡	⌈ ⌊ ⌈ ⌊	⌈ ⌊ ⌠ ⌡ . See note, below.	⌈ ⌊ ⌠ ⌡ . See note, below

Figure 2-4: Symbols in syntactic classes.

Notes:

- The symbol . denotes a conjunction only when it is not part of a number. It is part of a number when the character on either side of it is a numeral.
- ϵ \cap \cup The symbols ϵ \cap \cup are parsed as verbs even though no use has been defined for them.
- In APL the symbol \circ occurs only as part of the *dot* conjunction and so is a special case.²¹
- ∇ ∇ The symbols ∇ and ∇ invoke the ∇ -editor. If they occur in an APL sentence (except as part of a character constant), they are treated as undefined conjunctions.

The rules governing the use of these classes define the *syntax* of the APL language. In subsequent chapters, members of the various classes are described separately.

²¹ In "A Dictionary of APL" it is treated as a noun.

3 Nouns and Pronouns

A noun is a collection of items of data – numbers or characters – treated together as a whole. For example, in the sentence

`cost←index×+/3 1.4 19`

the list of numbers 3 1.4 19 is a noun.

A noun may be the *argument* of a verb; that is, the object to which the verb applies. In the foregoing, the noun 3 1.4 19 is the argument of the verb `+/`.

In general, when the interpreter *executes* (that is, *evaluates*) a sentence, it replaces each occurrence of verb-and-arguments by the resulting noun. It continues this process until no verbs are left, and the entire sentence has been reduced to a single noun.¹ Thus, executing a sentence usually requires reducing it to a noun, which is said to be the sentence's *value* (or *result*). When `index` has the value 2, the result of the sentence illustrated above is 46.8; that is, 2 times the sum of 3 1.4 19.

You may assign a name to a noun. When a noun has a name, you may refer to it by its name. However, a noun is not *required* to have a name. In the example, the noun 3 1.4 19 has no name. Nor is there a name for the sum of 3 1.4 19. However, the noun resulting from multiplying `index` by the sum of 3 1.4 19 is assigned the name `cost`. Thereafter, when you refer to `cost`, the interpreter substitutes for the name `cost` the noun 46.8. Since a name stands for a noun, in that sense a name is like a *pronoun* in natural language. In this manual, in places where no confusion would result, the terms *noun* and *pronoun* are often used interchangeably, since a pronoun must always be a name for a noun.

Rank and Shape

The items within an array are arranged in a system of axes or *Cartesian coordinates*. The *rank* of an array is the number of axes it has. The simplest array has zero axes and is called an *item* or, in mathematical terminology, a *scalar*.

In principle, an array may have any number of axes; however, as a practical matter, the APL interpreter permits no more than 63 axes.

¹Or no noun at all, when the sentence's root verb has no result.

A single item (say, the number 123.45 or the letter 'K') has rank 0: it has no axes. A list (say, the numbers 12 24.3 4.75 or the characters 'Mary Jones') has rank 1 because its items are spread along a *single* axis. A *table*, made up of rows and columns, has rank 2. And so on, for any number of axes.

Arrays are *rectangular*. The *shape* of an array is the number of positions along each axis; that is, the *length* of each axis. For example, in a 3-by-4 table (having three rows and four columns), every row has the same number of items (four), and every column has the same number of items (three).

The axes of an array are identified by number. The first axis is by convention "axis 1," the next is "axis 2" and so on.²

Reporting Shape and Rank

The monad ρ , pronounced *rho*,³ reports the length of each axis of a noun. Its result is a list containing one number for each axis. The value of each number indicates the *length* of the corresponding axis; that is, how many items lie along that axis. For example, when τ is a table with three rows and four columns:

```
       $\rho \tau$   
3 4
```

This is called "shape of τ ." Applying ρ again to find the length of the result of $\rho \tau$ (the shape of the shape of τ) tells you how many items there are in the noun $\rho \tau$:

```
       $\rho \rho \tau$   
2
```

Thus, two consecutive uses of monad ρ give you the *rank* of a noun.

Arrays and Cells

You may consider an array as a collection of *cells*. Each cell occupies the noun's *last* so-many axes. The number of axes devoted to a cell is arbitrary, but they have to be at the *end* of the list of axes. Suppose you want each cell to have k axes. Then the last k axes are said to be *rank- k cells*, or simply *k -cells*.

For example, suppose the noun a is created as follows:

² In a context where you have elected 0-origin counting, the first axis is axis 0, the second is axis 1, and so on. See the discussion of *index origin* in Chapter 5, "Verbs". Newer dialects of APL, such as J, use index origin 0 exclusively.

³ *Rho* is the name for the symbol. The verb it denotes may be used either as a monad or as a dyad. As a monad, the verb is often called *shape*; as a dyad, *reshape*. See the discussion of verb names at the start of Chapter 5, "Verbs".

```
a←2 3 4P'abcdefghijklmnpqrstuvwxy'
```

```
abcd
efgh
ijkl

mnop
qrst
vwxy
```

Then the list 'abcd' is a 1-cell of *a*. The two separate 3-by-4 tables are 2-cells of *a*, and the entire 2-by-3-by-4 collection is a 3-cell of *a*. Each of the individual letters is a 0-cell of *a*.

These are all valid ways of looking at the noun *a*. Whether you treat *a* as a single 3-cell, or a pair of 2-cells, or a 2-by-3 table of 1-cells, or a 2-by-3-by-4 array of 0-cells, does not depend on anything in *a* itself. How you look at *a* and partition its axes into cells depends on the verb you apply to *a*. It also depends on the way the verb is modified by the rank conjunction *⌵*. (See Chapter 6, "Adverbs and Conjunctions".)

The rank conjunction specifies how many of a noun's axes are used to form a cell. The cell axes have to be taken from the *last* of the noun's axes. Suppose *b* is a rank-4 array, and that the shape of *b* is the list 2 3 4 5. When you decide to partition *b* into cells of rank *k*, in effect you are taking the last *k* items from the list 2 3 4 5 and reserving them for cells.

When you treat the last *k* axes as cells, the noun may have other axes left over. The axes that come *before* the *k* axes you treat as cells are said to be the *frame* axes. The frame axes are the complement of the cell axes. For example, when the shape of *b* is 2 3 4, then *b* has:

Frame 2 3 4 relative to cells of rank 0 (each of which is an item)

Frame 2 3 relative to cells of rank 1 (each of which is a list of shape 4)

Frame 2 relative to cells of rank 2 (each of which is a table of shape 3 4)

An empty frame relative to cells of rank 3 (each of which — there is only one — is the entire 2-by-3-by-4 array).

Notice that an empty frame means that the entire array is treated whole, as a single cell.⁴ Figure 3-1 illustrates the alternative ways of partitioning a 2-by-3-by-4 array into cells.

⁴An empty frame has no frame axes. That is not the same thing as a zero frame — one of whose axes has length zero (and therefore has no cells).

Rank 0 cells				Rank 1 cells				Rank 2 cells			
0	1	2	3	0	1	2	3	0	1	2	3
4	5	6	7	4	5	6	7	4	5	6	7
8	9	10	11	8	9	10	11	8	9	10	11
13	16	19	22	13	16	19	22	13	16	19	22
14	17	20	23	14	17	20	23	14	17	20	23
15	18	21	24	15	18	21	24	15	18	21	24

Figure 3-1: Alternative ways of partitioning a 2-by-3-by-4 array into cells.

The number of cells that a frame contains is the *product* of the noun's *frame-shape*. When any of the frame axes has length 0, the number of cells it contains is zero. Such a frame is said to be a *zero frame*.

Complementary Partition

An array's cell rank is the complement of its frame rank. You can describe the partition by stating:

- the rank of each cell (in which case any leftover leading axes are part of the frame)
- or
- the rank of the frame (in which case any leftover trailing axes are part of each cell).

To describe a partition by specifying the number of frame axes, use a *negative* number. The number of frame axes is the magnitude of that negative number; for example:

Rank -1 The first axis is the frame. Each cell has whatever rank remains when the array's first axis is devoted to the frame and all the other axes are cell axes.

Rank -2 The first two axes are the frame. Each cell has whatever rank remains.

For example, within the rank-3 array *a* mentioned earlier, the list 'abcd' may be called a 1-cell of *a* or it may be called a -2-cell of *a*. Similarly, the two 3-by-4 tables within *a* may be called either 2-cells or -1-cells of *a*.

Major Cells

For any array, its 1-cells are its *major cells*. The number of major cells is the length of the array's first axis. A rank-0 array (that is, an item, having no axes) has a single major cell, itself.

Infinite Rank

When a verb has *unbounded*, or *infinite*, rank, it treats its entire argument as a single cell, regardless of the number of axes the array may have. Several verbs have infinite argument rank. All user-defined verbs have infinite rank.

APL does not have a symbol for "infinity." When you need to specify that a verb applies with infinite rank, any large number will do for the rank, provided it is not less than the noun's actual rank.

Types of Noun Items

An item may be:

- a *number*
- a *character*
- a *box*.

Homogeneity of Arrays

All the items in an array must be of the same type: numbers, characters, or boxes.

Within an array of boxes, each box may contain any type of array data (number, character, or box), with no requirement that the various boxes contain data of the same type.

Empty Arrays

An array is *empty* when one or more of its axes has length 0. In principle, the type of an empty array is immaterial. However, the verbs \succ and \uparrow and the derived verb $n\backslash$ are permitted to produce a non-empty array from an empty one, and when they do, the empty array's former type may again become evident.

To facilitate work with character arrays, the empty character list $''$, or any empty array resulting from an operation on a character array, retains its identity as type *character*.

All other empty arrays are numeric. Thus $(\iota 0) = 0\rho\omega$ for any ω , regardless of the type of ω (and even when ω is an array of boxes).

Numbers

During input or output, a number is represented by digits, combined as needed with a decimal point, a negative sign, or the letters *e* or *j*. A negative number has a leading *macron* (or "high minus sign"), as in $\bar{3}.2$ or $6.2e\bar{23}$.

A number may be written in any of the following forms:

Integer For example, $2\ \bar{256}$.

Real For example, $2.1\ 0.009\ \bar{2}.56$.

Exponential For example, $1.6e9\ 6.2e\bar{23}$.

Complex For example, $3j4.1\ 1.6e9j\bar{6}.2e\bar{2}$.

In writing the various items in a list of numbers, it is permissible to intermix forms. For example, the following is perfectly valid:

$x\leftarrow 1\ \bar{16}\ 2.56\ 2.08e17\ 3.1j\bar{6}.3$

In similar fashion, when the APL interpreter displays a list of numeric items, it chooses the form independently for each item and thus may also intermix formats.⁵

Although the interpreter permits mixed formats for entry or display, it stores all the members of an array in the same way. The effect of a sentence such as the one just shown is to create an array all of whose items are stored in the most demanding of the forms (see below).

Internal Representations of Numbers

The APL interpreter uses four different internal forms for the storage of numbers. The forms differ in the space per element they require (so the choice of internal type may have important consequences for storage). The four types are:

Boolean Zero or one. Boolean representation is used for a single 0 or 1 entered from the keyboard, or for the result of a proposition, with 1 for *true* and 0 for *false*. Certain verbs return Boolean results (for example, tests for equality and membership.)

Storage: Bitwise, 8 items per byte, plus overhead (see below).

⁵ Formats are maximized in the display of lists. In tables or higher-rank arrays, all items are currently displayed in the same format.

Integer A number with no fractional part and within the range that can be represented in 32 binary bits: -2^{31} to $2^{31} - 1$ (that is, -2147483648 to 2147483647).

Storage: 4 bytes per item, plus overhead.

Floating A number with a fractional part or an integer outside the range representable in *integer* format. Also known as *real numbers*. Floating point numbers may range in magnitude between $\pm 7.2370055773322621 \times 10^{73}$. The internal representation uses 14 hexadecimal digits, permitting a maximum precision of about 18 decimal digits.

Storage: 8 bytes per item, plus overhead.

Complex A number with both real and imaginary parts. The parts are written with the letter *j* between them. Each part is represented in Cartesian form, in the same way as a floating point number.

Storage: 16 bytes per item, plus overhead.

In addition to the space required to store its items, there is an additional overhead for system information, including the array's type, rank, and shape, amounting to at least $12 + 4 \times$ its rank.

Within a numeric array, all items are given the same type of internal representation (Boolean, integer, floating, or complex). For example, the list 1 2 is stored entirely in *integer* representation, even though one of its items (if alone) could be stored as Boolean; similarly, the list 2 2.3 is stored entirely as *floating*, even though one of its items (if alone) could be stored as an integer.

The existence of different internal schemes for representing numbers shows up directly in the space required to store them and may also affect the time required to execute certain verbs. In principle, internal type has no effect on the values that a verb can accept as arguments or the values that it returns as result. For example, a verb whose domain is limited to integers can accept any array whose values are numerically integral, regardless of whether the array is stored in the Boolean, integer, floating, or complex internal type.

The interpreter initially assigns the most compact representation that will embrace all the items in an array. Thereafter, upward conversion between types of numeric representation is automatic. If you write

```
x←0 1 1 0
```

the interpreter stores *x* in *Boolean* representation. If you then concatenate an integer to *x*, for example by

$x \leftarrow x, 2$

the interpreter converts the former value to *integer* representation while appending the integer 2. Similarly, if you then catenate a floating-point number, for example,

$x \leftarrow x, 1.9$

the interpreter represents the entire result in *floating* representation.

These conversions are automatic. No declaration of type is needed or allowed. There are no errors resulting from "mismatched" numeric types. The only practical consequences involve allocation of memory, and perhaps execution speed.

However, downward conversion of type, is not performed automatically. For example,

$x \leftarrow 1 \ 2 \ 3 - 0 \ 1 \ 3$

could be represented as Boolean. x will, in fact, be represented as integer.

Character Data

To enter characters from the keyboard, you enclose them in quotes; for example, as 'ABC' or 'Far away' or '3×\$6'.⁴ To represent the quote character itself, enter two consecutive quotes.

There is no implicit collating sequence for characters. When you grade character data, you must provide a reference alphabet to control the order.

APL Character Set

The APL interpreter represents each character internally as one 8-bit byte. There are thus 256 possible characters. Not all of them are displayable or enterable from the keyboard. Nor are all of them valid in a sentence to be executed.

The character set includes both conventional alphabetic and numeric characters and also characters for the additional symbols used in APL expressions. During output, a few characters are recognized as control characters (for example, *newline*, *line feed* or *backspace*). The bit-patterns that the APL interpreter uses to represent characters do not match the codes used in the EBCDIC or ASCII encodings.

⁴ Strictly speaking, this applies to sentences written during immediate execution or to sentences in the definition of a verb. During input solicited by Ω , the entire line is treated as characters and hence needs no quotes around it. See the section "Input and Output" later in this chapter.

Boxed Arrays

An item within an array may be a *box*. A box is an item in the same sense that a single number or character is an item: it has no axes, and it occupies a single position in the array's Cartesian framework. An array consisting of six boxes, arranged in two rows and three columns, has shape 2 3, in the same way as a 2-by-3 array of numbers or characters.

A box may contain within it an array of any rank, shape, or type. A box is thus a convenient way to place objects of arbitrary shape within the simple Cartesian framework of an array. To distinguish it from a noun that contains boxes, a noun whose items are unboxed numbers or characters is said to be *open*.

A box is created by the *box* monad \leftarrow . The result of \leftarrow is always an *item* and therefore has rank 0; for example:

```
PPX←'Now is the time'
```

```
0
```

Several ways to form an array of boxes are described in Chapter 5, "Verbs". For example, the *link* verb \triangleright joins a pair of open arrays to form a two-item list of boxes. Because \triangleright boxes its right argument only when the right argument is open, a sentence that links a succession of open arrays produces a list of boxes, thus:

```
Py←'Now'▷'is'▷'the'▷'time'
```

```
4
```

```

      y
|---| |---| |---| |---|
|Now| |is| |the| |time|
|___| |___| |___| |___|

```

Partitioning

Modifying the *box* verb with the conjunction *cut* produces the derived verb *cut-and-box*. It forms a box from each of the segments in its right argument, using the first cell of the right argument as the delimiter. This *partitions* the right argument into a list of pieces of the argument. For example, to box words delimited by blanks:

```
z←'1'←' Now is the time'
```

```
y←'Now'▷'is'▷'the'▷'time'
```

```
y≡z
```

```
1
```

* y and z match

```
y ≡≡0 z
```

```
1 1 1 1
```

* The items of y and z match

4 `y!<'time'` a <'time' is the fourth item

Figure 3-3 depicts a 2-by-3-by-4 array of boxes with two of them opened so you can see their contents.

Figure 3-3: A 2-by-3-by-4 array of boxes.

Display of Boxes

Whenever a sentence produces a result but does not assign a name to it, the interpreter displays it. This applies just as well to an array of boxes as to an array of numbers or characters. Such a default display has the same appearance as the result produced by the thorn monad `v`, described in Chapter 5, "Verbs".

The appearance of a display of an array of boxes is influenced by the value of the system noun `Ops` ("position and spacing").⁷ By setting the last two items of `Ops` negative, for example `Ops←0 0 -2 -2`, you cause the interpreter to show the boundaries of each box. That is particularly useful when you want to make the structure explicit. With the box boundaries thus made visible, the noun `x` (mentioned above) is displayed like this:

```
Ops←0 0 -2 -2
x
┌───┬───┬───┬───┐
│Now│is│the│time│
└───┴───┴───┴───┘
```

⁷ See Chapter 11, "System Nouns and Verbs" for the definition of `Ops`.

Packages

A *package* is a noun that in some respects resembles a *workspace*:

- The items within a package are selected by *name* rather than by position in a framework of *axes*.
- A package may contain both pronouns and user-defined verbs.
- A package is *not* an array. Hence, verbs that are defined on arrays are *not* defined on packages.

Within a package, the various named objects may be of any type, including not only nouns of any type, but also user-defined verbs. A name in a package may even have *no* referent, so that when the contents of a package are materialized into the workspace, an object having that name is expunged.

A package is useful to provide *overlays*. These permit an application designer to materialize in a workspace – perhaps dynamically, or within a local environment – whichever nouns or verb definitions the application requires, without altering the package from which they are taken. Often the source package resides not in the workspace at all but in a file outside the workspace.

A package is a data type independent of APL arrays, manipulable only by a set of specialized system verbs (`⊖pack`, `⊖pdef`, etc.). The contents of a package cannot be displayed directly. A sentence whose result is a package produces as display only the message:

****package****

To see the definitions of the objects stored in a package, you have to extract the packed items and then display them.

Verbs for manipulating packages are listed below, with square brackets indicating optional arguments. For detailed descriptions, see the entries for the individual verbs in Chapter 11, "System Nouns and Verbs".

[a] <code>⊖pack w</code>	Form a package.
[a] <code>⊖pdef w</code>	Define in the workspace objects from a package. (No result.)
α <code>⊖pex w</code>	Form a package by excluding some objects in a pack- age.
α <code>⊖pins w</code>	Form a package by merging two packages.
[a] <code>⊖plock w</code>	Lock the definitions of user-defined verbs in a pack- age.
<code>⊖pnames w</code>	Return the names of objects in a package.

[a] <code>Opnc w</code>	Return the name-class of objects in a package.
[a] <code>Oppdef w</code>	Like <code>Opdef</code> , but protect existing objects by defining only those names that do not conflict with names outside the package.
a <code>Opse1 w</code>	Form a package by selecting a subset of the objects in a package.
a <code>Opval w</code>	Return the value of a pronoun in a package.

Input and Output

This section deals with the conventions for displaying data at the screen and with entering data from the keyboard. See also the description of the *format verb* `f` in Chapter 5, "Verbs", and the description of the system verb `Ofmt` in Chapter 11, "System Nouns and Verbs".

Constants

A sentence to be executed may contain characters that represent a number or a list of numbers; similarly, a sentence may contain characters that denote the characters themselves, as text (rather than names or symbols). Such an entry is a *constant*; it states directly the value of a noun.

The interpreter considers a constant that consists of a single number or character to be an item. An entry that consists of more than one number or character is a list. For example, in the following, *a* is an item and *b* is a list:

```
a←126.2
b←126.3 14 127
```

There is no way to write a constant that has more than one axis. (See "Creating Higher-Rank Arrays," below.)

During entry, blanks separate successive numbers in the same list; extra blanks are not significant.

You may write numbers in different formats within the same list: some in integer format (without a decimal point), others in real format, yet others in exponential format or complex format, as convenient or appropriate for the values you are writing. For example:

```
c←1 .3 0.0125 2.62e-3 262a2 1.2e4j3
```

A negative number is preceded by the macron, as for example ⁻5. The macron or "overbar" symbol is *not* a verb, but one of the characters used in writing certain numbers, just as the decimal point or the letters *e* or *j*

occur in certain numbers. When several numbers are negative, each must have its own macron. By contrast, the symbol $-$ denotes the verb *minus* or *negate* and, like other verbs, applies to an entire array. The expression

```
x←~12 1.05 4000
```

gives the name *x* to a three-item list; only the first item is negative, whereas

```
x←-12 1.05 4000
```

creates a three-item list all of whose items are negated by the verb $(-)$ that precedes them.

To differentiate characters from numeric data, you enclose a character item (or a character list) in quotes. The beginning of a character constant is marked by a single quote mark. Everything you enter after that (for the balance of the line) is treated as characters until you enter a matching single quote to end the string of characters. Once you have started a quote, two consecutive quote marks indicate the quote character itself. (See the discussion of quote in Chapter 2, "Grammar".) Thus, in general, numbers are separated by blanks but characters are not. Extra blanks between numbers are not significant. Each of the following creates and names a seven-item list:

```
x←25 ~2.4 1e9 2.7e~24 123456789 70.2j1.4 0
y←'Thanks!'
z←'I can't'
```

Within the zone enclosed by quotes, blank is a character like any other. When you put several consecutive blanks in a character constant, each of them is an item in the same way as any other character in the string.

When the interpreter displays character data, it does not surround it with quotes or double the quote mark, hence:

```
z
I can't
```

A line containing an odd number of quotes (not counting quotes that occur within a comment) is ambiguous. The interpreter cannot tell which characters are inside and which are outside the quotation. It rejects such a line as a *syntax error*, without executing any of it.

Creating Higher-Rank Arrays

A constant is limited to a *single item* or a *list*. To supply the value of a table (or any array with more than one axis) you have to enter it as a list and then restructure it with a verb such as *reshape* to organize the items into a higher-rank array. Thus:

```

t←3 4P'The fat cat.'
t
The
fat
cat.

```

Creating the Value of a Box

A boxed constant, like a higher-rank constant, is written as a phrase that includes a verb that forms boxes. In the following example, the verb *link* boxes and joins the constants to form a three-item list of boxes:

```

h←'Paul' ⋈ 'Hempstead' ⋈ 1933 8 24
3 1Ph
Paul
Hempstead
1933 8 24

```

Display of Nouns

Unless the noun produced by evaluating a sentence is assigned a name, the interpreter displays the noun's value. This is called *default display*. It occurs with no need for a "display" verb and requires no instruction regarding format.⁸ The display of numbers is conditioned by the visible value⁹ of the system nouns *Ⓛpp* (printing precision) and *Ⓛpw* (page width); the position and spacing of boxed arrays is controlled by the visible value of the system noun *Ⓛps*.

The interpreter displays a list (that is, an array having only one axis) horizontally. It inserts a blank to delimit a number from its neighbor. However, it does not put blanks between the items of a character array. That way, characters can be placed side-by-side to form words, but numbers (which often require several characters to write) do not run together. For example

```

n←123,45,67.8

```

forms a three-item numeric list. When the interpreter displays the list, it introduces blanks to separate the items:

```

■
123 45 67.8

```

But it does not insert blanks to separate the items when they are characters:

⁸ The default display has the same appearance as the result of the monad *Ⓛ*, described in Chapter 5, "Verbs". That is, present in the workspace and not shadowed by the localization of names.

```
C~'H','e','l','l','o',' '
C
Hello!
```

Position and Spacing in an Array of Boxes

During display of an array of boxes, the system noun `Qps` affects the position and spacing of the boxes.¹⁰ In a clear workspace, the value of `Qps` is `1 1 0 1`.

When the interpreter displays a table of boxes (or any array of rank greater than 1), it first formats each of the individual boxes separately. It then assembles those separate displays into a grid that retains the overall rectangular shape of the array. To preserve the alignment of the grid, it pads the width of each small box to match the width of the widest box in that column. Similarly, it pads the height of each small box to match the height of the tallest box in that row. The shading in Figure 5-10 illustrates the resulting plaid pattern.

Because each item is located in a display cell whose height is the maximum in its row and whose width is the maximum in its column, an item may be assigned to a display cell with more rows or columns than it would need on its own. The first two elements of `Qps` specify how an undersize item should be positioned in the space assigned to it. The values `1 1` mean it should go in the top left corner of its box, with any extra space below and to the right.¹¹

The last two elements of `Qps` control the way adjacent boxes are separated. The third element sets vertical spacing and the fourth horizontal. The magnitude is the number of additional print positions that should separate adjacent boxes. The default is zero print-positions vertically and one print-position horizontally. Thus:

```
Q Q n
Hello! Hello! 123 45 67.8
```

The details of numeric formats, and the arrangement of boxed items in a grid for displaying arrays of rank 2 or higher, are described in the section on `v` in Chapter 5, "Verbs".

¹⁰ See the sections on `v` in Chapter 5, "Verbs" and the description of `Qps` in Chapter 11, "System Nouns and Verbs".

¹¹ For discussion of these values, see the description of `v` in Chapter 5, "Verbs" and the description of `Qps` in Chapter 11, "System Nouns and Verbs".

Separating Successive Columns of a Numeric Array

In displaying a numeric array of rank 1 (a list), the interpreter formats each item individually and separates successive items by one blank.

In displaying a numeric array whose rank is 2 or greater, the interpreter decides for the array as a whole whether to use real or exponential format. When it uses real format, it picks a total width and selects the units position once for the entire array, so that all columns are in a common format.

Separating Successive Planes of Higher-Rank Arrays

A rank-3 array appears as a set of tables. That is, a 3-by-4-by-5 array looks like three 4-by-5 tables, one above the other, with a blank line between the first and second and a blank line between the second and third.

During display, an extra line (or lines) is inserted between successive sub-arrays. One blank line is inserted between successive rank-2 sub-arrays, two blank lines between successive rank-3 sub-arrays, and so on.

If you examine the result of an expression such as

```
X←VArray
```

where *Array* is an open array with more than two axes, you find that *x* has the same rank as *Array*. The display of *x* shows blank lines between its successive tables by virtue of the rank of *x*, not because *x* contains any added *newline* characters.

However, when the system formats an array of boxes, the entire result is represented as a table. In that case, additional rows of blanks are inserted to represent the separation between planes. When *A* is a 2-by-3-by-5 array of characters, and *⌈ps* has its default value,

```
⌈←A
```

represents *A* by a seven-row table whose middle row contains only blanks.

Folding Wide Displays

An array returned by the formatting verbs *⌈* or *⌈fmt* is arranged without regard for the width available to display it. However, when you have output displayed on the screen, APL takes into account the length of the line available for display. The maximum number of print positions on a line is the visible value of the system noun *⌈pw* (*page width*). The default, *⌈pw* in a clear workspace is 80. You may set it as low as 30 or as high as 250.

The effect of *⌈pw* depends on the rank and type of the array being displayed.

Folding a Character Array

In displaying a character array, the interpreter prints no more than $\lfloor \text{Opw} \rfloor$ characters on a line. As soon as it finds it has already put $\lfloor \text{Opw} \rfloor$ characters on the current line and the next character is something other than *newline*, it forces a new line. It indents the continuation line by six spaces.

A character array is broken solely by the number of characters on the line. No attempt is made to break at a word boundary or other "meaningful" place.

When the array contains an explicit *newline* character ($\lfloor \text{Av} \rfloor[156+\lfloor \text{Io} \rfloor]$, it is obeyed. That is, the next character is displayed at the left margin of the line below, and the length of the current line is counted from there. Thus, a list of characters containing explicit *newlines* appears with the lines folded at the *newline* characters or at $\lfloor \text{Opw} \rfloor$, whichever comes sooner on each line.

Folding a Numeric List

A numeric list is displayed such that each line contains as many numbers as will fit without separating the characters that represent a single number. Thus, the number of characters on a line is at most $\lfloor \text{Opw} \rfloor$, but may be fewer. Since the number of characters required to represent each number may vary, the number of numbers displayed on a line may vary. So may the number of characters on a line. In rare cases, with values of $\lfloor \text{Opw} \rfloor$ less than 50, a single complex number may be split across two lines.

When a line that will not fit within $\lfloor \text{Opw} \rfloor$ is broken, the next line, and any subsequent lines that are continuations of the original line, are indented by six positions.

Folding a Numeric Table or Higher-Rank Array

A numeric table, or a numeric array of any rank higher than 1, is arranged so that all columns have the same width. APL figures out the number of print positions that would be required if *all* the items were in a single column. It uses the field width thus calculated for all columns of the array (regardless of the actual widths of numbers in a particular column).

Using the field width just calculated, it starts at the beginning of each row and writes as many fields as will fit within $\lfloor \text{Opw} \rfloor$. Then it moves to the next line, indents six positions, and prints as many of the remaining fields as will fit within $\lfloor \text{Opw} \rfloor - 6$. It continues in that fashion until the entire row has been printed. Then it prints the next row.

Folding an Array of Boxes

For folding in response to `⌵pw`, the display of an array of boxes is treated in the same way as character data. That is, each line is broken after `⌵pw` characters or at a *newline* character (whichever comes first), and the continuation is indented by six positions. APL makes no attempt to preserve the boundaries of boxes when `⌵pw` requires folding.

Display of an Empty Array

An empty list appears as a blank line; a line on which nothing is printed. An empty table, or an empty array of any rank greater than 1, produces no display at all (not even a blank line).

This is true not only for a table with zero rows, but also for a table with a positive number of rows but zero columns. Indeed, there is no display at all for any array whose rank is 2 or greater when zero is the length of any `axis`.

Interface Nouns: `⌵` and `⌶`

The symbols `⌵` and `⌶` denote the system nouns *quad* and *quote-quad*. They act like nouns shared with the session handler. The action of these two system nouns depends on whether they are *used* or *set*. A noun is said to be *set* when it is immediately to the left of the copula `←`, as in:

```
x←foo ⌵←analyze x
```

It is said to be *used* when it occurs anywhere else, as in:

```
x←foo analyze ⌵
```

Assigning a value to `⌵` or `⌶` causes the noun thus assigned to be displayed.

Evaluated Input

In a sentence to be executed, when the symbol `⌵` occurs anywhere *except* immediately to the left of the copula, `←` (assuming no redundant blanks), it represents the value of an input expression to be obtained from the session handler.

When, in the course of evaluating a sentence, the interpreter encounters the `⌵` symbol used in this way, it displays the prompt

```
⌵⌵
```

and awaits one line of entry. It evaluates the next line it receives in the same way that it would evaluate a line entered during immediate execution.

That done, it substitutes the resulting value for the \square symbol and resumes execution of the sentence that contained \square . For example, suppose you are computing the growth factor of an investment that earns interest for 20 years, compounded monthly. You want a sentence that will prompt you to fill in the annual interest rate but will accept an expression rather than just a number. The following illustrates the use of \square to solicit a sentence whose result is then used in evaluating another sentence.

	$(1+\square)*12\times\text{Years}=20$	aExpression containing \square
\square :		aPrompt for input
	$0.08+12$	aOne month of 8% annually
	4.926802771	aResult

The presence of \square in the phrase $(1+\square)$ causes APL to issue the prompt \square :

In response to the prompt, you enter $0.08+12$, to represent the monthly interest described by an annual rate of 8%. The interpreter evaluates $0.08+12$ and substitutes the result 0.006666666667 for \square so that it can evaluate $1+\square$. That done, it raises 1.0066666667 to the power 12×20 and prints the result, indicating that the value after 20 years is nearly five times the initial amount.

Input in Response to \square

In response to the \square : prompt, you enter one *line* of input. It may contain any executable sentence,¹² invoking any primitive verb or any user-defined verb whose name is visible. When evaluation of that sentence is complete, the interpreter passes its value back to the expression that contained the \square . In the example, the result is used as the right argument to \times , so the result could be anything in the domain of \times .

When, in response to the \square : prompt, you enter a line containing several sentences separated by diamonds, the interpreter evaluates all of them, but the value substituted for \square is the value returned by the *last* sentence to be executed.

When, in response to the \square : prompt, you do something that produces no sentence to evaluate (for example, you simply press *Enter* without writing a sentence, or execute a system command), the interpreter repeats the \square : prompt for evaluated input.

It is acceptable to enter a system command during \square -input. The interpreter carries out the command. However, since in this case the command does not satisfy the request for an input sentence, the interpreter reissues the

¹² Or several sentences separated by diamonds.

□: prompt. You could exploit this to copy into the workspace something that was not initially present and then use the object thus copied in your response to the prompt. For example:

```
Supply data for analysis:
□:
    datapoints
value error
    datapoints
A
□:
    )copy savedwork datapoints
saved 1988-02-27 23:11:15
□:
    datapoints
...
```

When, in response to the □: prompt, you enter ↵ alone (the naked right arrow), the interpreter abandons both the execution of □ and the execution of the sentence that contained it, as well as anything else pending, back to the previous immediate-execution entry from the keyboard. (See Chapter 8, "Control of Execution".) A gentler method of halting execution is to enter an *input interrupt* (see below). Execution of)load also abandons execution of the sentence, as well as the entire application.

Character Input

In a sentence to be executed, when the symbol □ occurs anywhere *except* immediately to the left of the copula, assuming no redundant blanks, it represents a character list to be obtained from the keyboard. The interpreter displays no special prompt (except as may be produced by □ output, described below). The interpreter awaits the entry of one line from the keyboard. It treats that line as characters (even if what you then enter looks like a sentence or a system command). It substitutes the resulting characters for the □ symbol and resumes execution of the sentence that contained □. For example:

```
'Enter data:' * (⌈⌈□⌋), ' received.'
```

Enter data	⌈Display of the first sentence
abcdefghijklmnopqrstuvwxyz	⌈Your entry
26 received.	⌈Display from ⌈⌈□⌋

Escape from ⎵-Input and ⎵-Input

While the interpreter is waiting for one line of character or evaluated input, you can signal an *input interrupt* by typing CTRL+c and thereby *escape* from the request for input.

Sending an input interrupt at any point during your response to a request for ⎵-input – that is, at a keyboard any time *before* you press *Enter* or *Return* – causes the interpreter to abandon execution of the sentence that contains the ⎵ or ⎵ and to halt execution of the program that contains that sentence. Any characters you may have already entered on the same line are lost. However, if ⎵trap has been set to respond to the input interrupt event, the trap may make it difficult or impossible to escape. See Chapter 9, “Event Handling”.

Explicit Output from ⎵ and ⎵

When the system name ⎵ or ⎵ occurs immediately to the left of the copula +, the interpreter displays the value of the noun to the right of the arrow. A display produced this way is identical to a display produced by default output or by the monad ⍒, with one important exception: output produced by ⎵+ is not followed by a *newline*, whereas the interpreter automatically supplies a *newline* following default output or output elicited by ⎵+.

A series of sentences produced by ⎵ appear on successive lines, whereas a series of sentences produced by ⎵ output may accumulate on the same line. This allows a line of output to be built up from the results of several expressions. For example, a program might contain the following sequence:¹³

```
[ ] ...  
[ ] year←years[i]  
[ ] dist←recordmiles[i]  
[ ] ⎵←year  
[ ] ⎵+' 's record was '  
[ ] ⎵←dist×1.6  
[ ] ⎵+' km.'  
[ ] ⎵+'Today' 's distance: '  
[ ] ⎵←todaymiles×1.6  
[ ] ⎵+' km.'  
[ ] ...
```

When that fragment of the program is executed (with appropriate values for the various names), the separate pieces of ⎵ output fit together thus

¹³ These have to be in a program. If you were to enter these lines from the keyboard for immediate execution, the interpreter's prompt for your next entry would obscure the effect.

However, if you move the cursor leftward into the prompt zone and there enter some other characters (overwriting the characters used in the prompt), the characters you substitute are reproduced in the result.

Discarding the Prompt

When you have no interest in the prompt or in entries placed in the prompt zone, you may simply discard them from the result. Phrases such as the following are common:

```
prompt←'Supply name: '  
name←(⍉prompt)⋄⍉-⍉←prompt
```

Alternatively, you can exploit a quirk of ⍉arbout to eliminate the prompt from the result:

```
prompt←'Supply name: '  
⍉←prompt ⋄ ⍉arbout '' ⋄ name←⍉
```

Interposing any use of ⍉arbout between the input and output uses of ⍉ discards the output from the ⍉-input buffer and prevents the prompt zone from being treated as part of the input line. (The verb ⍉arbout is described in Chapter 11, "System Nouns and Verbs".)

4 Naming Nouns and Verbs

This chapter discusses how names are used and the means by which nouns and verbs acquire names.

←

Copula

The left arrow ← assigns a name to something. For example

```
x←analyze data
```

gives the name *x* to the noun that results from evaluating the expression

```
analyze data
```

The symbol ← plays in APL the same role that the copula “is” plays in English. An expression such as

```
area←6×8
```

is often read as “Area is six times eight.” Because the arrow ← assigns a name to an object, it is often called *assignment*.

Once a noun has been named, further reference to the name is a reference to the noun’s value; for example:

```
area←6×8
area
Ⓜ
area←0.5
6.92820323
```

Workspace: The Universe of Names

In order to evaluate a sentence that contains names, the interpreter requires some means of keeping track of the names that have been defined and what each name refers to. The mapping from names to their referents is provided by the *symbol table*. The set of all names maintained by a symbol table, along with their meanings, is called a *workspace*.¹

¹ In many other computer systems, the names used by the various programs are harmonized by a process called *linking*: the program that links separate components so that they can be used together is called a *link editor*. In APL systems, the consistent use of names is provided directly by storing objects in a workspace whose common symbol table gives the benefits of linkage without any specific process of link editing.

A workspace is not only the domain in which a common set of names is maintained by a symbol table, but also a block of physical storage. The area of the computer in which computation takes place is called the *active workspace*. The system command `)save` acts aside a copy of the active workspace's symbol table and all the objects referred to in it and retains it in inactive permanent storage. A workspace is thus both the conceptual universe in which names have meaning and a unit of storage. By *saving* a workspace, you set aside a copy of it. By subsequently *loading* a saved workspace, you restore in the active workspace all the names and all their referents as they were at the time the workspace was saved.

Localization of Names

A user-defined verb² may declare certain names to be *local* to itself. This means that the verb (or any verb it invokes) may make its own use of the names local to it, independent of any use those names may have outside the verb. Localization has these effects:

- It assures the verb's author that internal names needed by the verb will be available to it.
- It protects names in the workspace from possible conflicting uses within the verb's definition.
- It hides more global use of those names, if any, since from within a verb (or any verb it invokes), only the most local use of a name is visible.
- It cleans up after execution of a verb. When execution of a verb is complete, that ends its local use of names; the named objects it created vanish, and the interpreter frees any storage it had devoted to them.

A name is made local to a verb by appearing in the verb's *header*. The names used for the *arguments* and *result* of a user-defined verb are automatically local to it. So are any *line labels* used in the verb's definition. (Localization of names is discussed further in Chapter 7, "Verb Formation" and Chapter 8, "Control of Execution".)

When none of the currently-active verbs has localized a particular name, that name is *global* to the workspace. But when a name has been localized in a defined verb currently being executed, that local use is understood.

When a name is *not* local to the current verb, but *is* local to a pendent verb (a verb whose execution has been started but not completed), the use local to the pendent verb is understood.

² See Chapter 2, "Operators" and Chapter 7, "Verb Formation".

A declaration of local use prevents seeing, changing, or creating a use of that name at a more global level. (It is the declaration that counts; it does not matter whether the localized name has actually been used.) Local use blocks the view of more global use; the most local use of a name is sometimes called the *visible* use of the name; a more global use is called a *shadowed* occurrence of the name.

Reassignment and Name Conflicts

When you use the copula to name something, the name to the left of the arrow must be *free for use*; that is, it must have no visible use as a verb or as a label.

- When there has been no prior use, the copula assigns the name to the left of the arrow to the noun to the right of the arrow.
- When the name is already in use and refers to a noun, the value to the right of the \leftarrow replaces the former value. (That is why the name of a noun is also called a *variable*: its value can be changed at will.)

Names for User-Defined Objects

Both nouns and verbs may be given arbitrary names. As mentioned earlier, a noun is assigned the name that appears to the left of the \leftarrow . Verbs may also be named, but by a different mechanism (described in Chapter 7, "Verb Formation").

A *name* must start with a letter of the alphabet; subsequent characters in a name may be letters or numerals. The symbols Δ and δ are both permitted in names in the same way as letters. A name may not contain more than 77 characters.

The symbols α (alpha) and ω (omega) may also be used as names, but only when used *alone*, and not as part of a longer name. There are no rules regarding the uses to which you put the names α and ω , but by convention α is used as a generic name for a verb's left argument, ω for a verb's right argument.

Since the arbitrary name assigned to a noun is a shorthand reference to the noun, the name serves as a *pronoun*.

APL systems have little that corresponds to the *declarations* of other languages.¹ You do not have to declare the type of noun to which a name will refer, or its size. When you use a name, the interpreter simply notes

¹ For example, in languages such as C or Fortran, when you write a program you have to tell the compiler in advance what names you plan to use and the type and rank of each. They also require you to state (explicitly or implicitly) the maximum shape that each object will have, so that the compiler can set aside space for it.

the use made of it. The value to which a pronoun refers may be reassigned at any time. Reassignment may change its type, rank, or shape, as well as its value.

The only form of declaration is *localization* of a name to the definition of a verb. Names that are *local* to the definition of a verb must be declared as part of the verb's definition.

Indexed Assignment

The name to the left of the \leftarrow may be modified by index brackets, in an expression of the form:

$$x[i] \leftarrow b$$

The effect is to produce a new version of x in which the items at position i are taken from b , while the others are retained unchanged from x .⁴ Indexed assignment is also discussed as part of the description of indexed selection in Chapter 5, "Verbs".

Indexed assignment requires that:

- The array x must already exist.
- The expression within brackets must be appropriate to the rank of x (that is, must have the right number of semicolons: "1+PPX").
- The values of the indexes $[i]$ must be valid, given the index origin and the shape of x .
- The shape of b must match the shape implied by the index expressions within the brackets. b may be a single item, in which case it is inserted at *all* the locations indicated.⁵
- x and b must be of the same type (numeric, character, or box).

The Result of Assignment

When a verb occurs to the left of an assignment, the verb's argument is the result of the assignment. The result of assignment is the noun to the right of the \leftarrow . For example, in the sentence

$$3 \times x \leftarrow \text{analyze data}$$

the right argument of \times is the result of *analyze data*. Such a sentence can be read, "Three times x , which is *analyze data*."

⁴ In "A Dictionary of APL", this is achieved by $b \uparrow \{ \} x$, which has the advantage that the result is the entire modified array x , whereas the formal result of $x[i] \leftarrow b$ is b .

⁵ The interpreter also tolerates a mismatch between the ranks of b and x , but only when the additional ones are of length 1.

This is equally true for indexed assignment. In the sentence

$$3 \times x[i] \leftarrow a$$

the right argument of \times is the value of a (and not the value of x).

Multiple Assignment

A sentence may contain several assignments in a row. For example,

$$x \leftarrow y \leftarrow z[i] \leftarrow a$$

assigns the value of a to the name x and also to the name y . It also replaces the value of the sub-array $z[i]$. This does not make x and y synonyms; in particular, if you subsequently change the value of x , the value of y does not change.

Sentences Producing No Display

The interpreter displays the result of every sentence *except* a branch, an assignment, or one containing a root verb that does not return a result.*

An assignment sentence is a sentence that has \leftarrow at the root. In an assignment sentence, the name to the left of the copula is assigned to the noun to the right, but there is no display.

Placing \vdash or \Downarrow to the left of the principal assignment permits the same sentence to assign a name and display its value:

$$\Downarrow x \leftarrow (15) \leftarrow . = 15$$

```
1 0 0 0 0
0 1 0 0 0
0 0 1 0 0
0 0 0 1 0
0 0 0 0 1
```

* Types of sentences and a sentence's root verb are discussed in Chapter 2, "Grammar". Branch is discussed in Chapter 6, "Control of Execution".

Other Mechanisms that Produce Named Objects

As discussed in the first part of this chapter, the copula `←` assigns the name at its left to the object at its right. Other mechanisms that may also produce a named object are the following:

- | | |
|---|---|
| <code>⌊fx</code> | As a side-effect, these system verbs create a verb from a right argument that includes both the verb's definition and its name. The verb thus created becomes the <i>local</i> use of the name. (See Chapter 7, "Verb Formation" and Chapter 11, "System Nouns and Verbs".) |
| 3 <code>⌊fd</code> | |
| <code>v-editor</code> | The <code>v-editor</code> (invoked by the symbol <code>V</code>) creates a verb (or modifies an existing verb). The name of the verb appears in the top (header) line of the definition in the same manner as for <code>⌊fx</code> or <code>⌊cr</code> . The verb thus created becomes the <i>global</i> use of the name. (See Chapter 7, "Verb Formation".) |
| <code>)copy</code>
<code>)pcopy</code> | These system commands copy into the active workspace some or all of the names in the specified workspace and the objects to which the names refer. The objects thus defined become the <i>global</i> uses of the names. (See Chapter 12, "System Commands".) |
| <code>⌊pdef</code>
<code>⌊ppdef</code> | This system verb materializes in the workspace nouns or verbs stored in a package. The objects thus materialized become the <i>local</i> uses of the names. (See Chapter 11, "System Nouns and Verbs".) |

5 Verbs

This chapter describes each of the *primitive verbs* of APL, together with a few examples to illustrate its use. It also describes the indexing primitives. It includes every verb denoted by an APL *symbol*. However, this chapter does not include the *system verbs*, which are denoted by a *distinguished name* beginning with \square (such as \square read). System verbs are described in Chapter 11, "System Nouns and Verbs".

There is no inherent order for the symbols; they are arranged rather arbitrarily. The familiar $+$ $-$ \times \div come first. After that, symbols that are similar in appearance are grouped together, so that \equiv comes next to $+$; $*$ \circ are adjacent; and so on.

Names are given with the descriptions. Note, however, that a symbol may be associated with several names. (That is why they are not in alphabetical order of their names.) The descriptions may distinguish between:

- a name for the verb's *symbol*
- a name for the *dyad*; that is, the case when the verb is used with an argument on either side
- a name for the *monad*; that is, the case when the verb is used with a single argument.

The variety of names reflect the wide variety of names in common use. "A Dictionary of APL" proposes short names borrowed from a variety of English contexts. In some cases, those are included here, along with alternatives used in programming or mathematics.

In chemistry, the terms *monad* and *dyad* refer to objects having valence 1 and valence 2 respectively. That is how they are used here. Thus, the dyad \div is *divide* (as in $a \div b$), while the monad \div is *reciprocal* (as in $\div x$).

In the descriptions, the following symbols appear:

- α The verb's left argument.
- ω The verb's right argument.

Default Argument Ranks

A verb's *rank* is the number of axes in each argument cell.

Whenever you apply a verb to an argument of rank greater than the rank for which the verb is defined, the “extra” axes are treated as *frame axes*. The verb is applied independently to each cell within that frame. The rank conjunction \bar{v} (see Chapter 6, “Adverbs and Conjunctions”) can impose on any verb the specific argument rank specified by the noun to the right of \bar{v} .

In principle, every verb has a *default argument rank*. When you use the verb *without* explicitly saying what argument rank you want, APL assumes you mean the default argument rank. The default argument ranks are shown with the description of each verb. They are also summarized in Figure 5-1.

Argument rank is shown here (and in the argument of the rank conjunction \bar{v}) as a three-item list of integers. The items are:

- *Monadic rank*. Rank of an argument cell when the verb is used with one argument.
- *Left dyadic rank*. Rank of a left argument cell when the verb is used with two arguments.
- *Right dyadic rank*. Rank of a right argument cell when the verb is used with two arguments.

Agreement

The arguments of a dyad must have frames whose shapes *agree*. The two frames agree when:

- they have the same shape; that is, the same number of axes and the same length along each axis
- or
- one frame is empty; that is, has no axes.

When a frame is empty, the argument consists of a single cell. When one argument has an empty frame but the other does not, the frame that is not empty establishes the frame for the result. The single cell from the empty frame is paired with each of the cells in the other argument.

Scalar Verbs

In mathematics, a *scalar* is an object that has no axes (in this manual, usually called an *item*). A *scalar verb* is one that is rank-0 and returns a rank-0 result.

Because a scalar verb is defined without reference to axes, when you apply it to an array argument, *all* the argument's axes are *frame* axes. Therefore, the verb applies independently to each of the items throughout the frame.

When a scalar verb is used dyadically, the usual rules apply: either the two frames must have the same shape or one of them must contain only a single item, to be paired with every cell in the other argument. For example, adding the numbers contained in frames of length 3 produces three independent additions of the corresponding cells:

```
      1 2 3 + 12 5 20
13 7 23
```

That is because 1+12 is 13, 2+5 is 7, and 3+20 is 23.

Extending the Empty Frame

When one frame is empty, the single cell corresponding to that empty frame is paired with each cell in the other argument; the empty frame is said to be *extended* to match the frame of the other argument. The result frame has the same shape as the non-empty argument frame. This extension is illustrated in the following examples for addition:

```
      111 + 4.9 ^0.012 34
115.9 110.988 145

      4.9 ^0.012 34 + 111
115.9 110.988 145
```

Unbounded Rank

A verb may have *unbounded* rank (sometimes called *infinite* rank). When a verb has unbounded rank, no matter how many axes the argument has, they are all treated as part of a single cell. In the descriptions that follow, unbounded default rank is denoted by the ∞ symbol.

Unspecified Rank

For some verbs, no default argument rank has yet been specified. (The fact that some argument ranks remain unspecified is not a feature of the language, but a limitation of the current implementation.) You can still use the rank conjunction \wedge to specify a verb's argument ranks, or you can supply an argument of the usual rank. But if you apply such a verb to an argument that has more axes than the "usual" case, APL does not know

how to partition the axes into frame and cell. It reports a *rank error*. The verbs in Figure 5-1 whose entries contain an asterisk (*) are those for which a default rank has not yet been specified.

Reduction and Identity Elements

The class of derived verbs called *reductions* (see Chapter 6, "Adverbs and Conjunctions") applies the same verb between each of the major cells of its argument. For example, if an array X consists of three major cells X_1 , X_2 , and X_3 , then the f reduction of X , written $f\overleftarrow{X}$, is computed by:

$$X_1 \overleftarrow{f} X_2 \overleftarrow{f} X_3$$

A reduction applies to as many cells as the argument has; the expression $+\overleftarrow{X}$ computes the sum of two cells when X has two cells, the sum of three cells when X has three cells, and so on.

The verb used in a reduction is a dyad. Reduction is valid even when the argument consists of only one cell, or zero cells. What does it mean to apply a dyad to one cell, or to no cells? Ordinarily, "the sum of one thing" might seem nonsensical, and "the sum of no things" even more so. A useful generalization is obtained by the following rules:

- When ω contains only one major cell, the result of any reduction is ω .
- When ω contains no major cells, the result of any reduction of ω is the verb's *identity element*.

The reason for this becomes apparent when you consider how a final result is constructed from a set of partial results. It is often useful to partition a task; that is, to perform the task for part of the data, then another part, and so on. A final step consolidates the results from the parts. Partitioning is possible when a simple rule relates the result obtained from the various partitions to the result for the array as a whole. For example, if an array has five cells, you could sum the first two cells, then the last three, and finally sum those results to get the overall sum.

$$(\text{Sum of all five}) = (\text{Sum of first two}) + (\text{Sum of last three})$$

$$(\text{Sum of all five}) = (\text{Sum of first three}) + (\text{Sum of last two})$$

... and so on.

More generally, you should be able to split the five cells anywhere; summing the separate partitions and then summing the results should still give you the same result in the end. This principle helps define what reduction should mean when it is applied to one cell, or no cells. Generalizing from the preceding equation, we get the following:

Verb	Monad Rank	Dyad	
		L Rank	R Rank
+	0	0	0
-	0	0	0
×	0	0	0
÷	0	0	0
■	2	∞	2
*	0	0	0
⊙	0	0	0
○	0	0	0
⌈	0	0	0
⌊	0	0	0
!	0	0	0
?	0	*	*
=	∞	∞	∞
<	∞	0	0
>	0	0	0
≡	Undefined	0	0
≠	Undefined	0	0
≡	Undefined	0	0
≡	Undefined	∞	∞
~	0	Undefined	Undefined
⌘	Undefined	Undefined	Undefined

Verb	Monad Rank	Dyad	
		L Rank	R Rank
⌵	Undefined	0	0
⌶	Undefined	0	0
⌷	Undefined	0	0
⌸	Undefined	0	0
⌹	∞	∞	∞
⌺	∞	∞	∞
⌻	Undefined	∞	∞
⌼	Undefined	∞	∞
⌽	∞	*	*
⌾	*	Undefined	Undefined
⌿	∞	∞	∞
⋈	∞	∞	∞
⋉	∞	∞	∞
⋊	∞	*	*
⋋	∞	*	*
⋌	∞	*	*
⋍	∞	*	*
⋎	Undefined	*	*
⋏	∞	*	*
⋐	∞	∞	∞
⋑	∞	∞	∞
⋒	∞	*	*
⋓	Undefined	0	∞
⋔	Undefined	∞	∞
⋕	*	*	*

Undefined: No meaning established for this verb form.

*: This verb form has meaning, but no default argument rank has been specified for it.

Figure 5-1: Default argument ranks of primitive verbs.

(Sum of all five) = (Sum of first one) + (Sum of last four)

(Sum of all five) = (Sum of first none) + (Sum of last five)

It becomes evident that "the sum of the first one cell" should be the first cell itself. The sum of no cells should be something that makes no difference, since "sum of the last five" already gives the result "sum of all five."

For a particular dyad, the identity element is the value which, when it is one of the verb's arguments, guarantees that the verb's result is equal to the other argument. 0 is the identity element for addition because $0 + \text{anything}$ gives you *anything*, unchanged. Similarly, 1 is the identity element for multiplication, because $1 \times \text{anything}$ gives you *anything*, unchanged.

For some verbs, there is no identity element. For others, there is a right identity but not a left. For example, $\text{anything} + 1$ gives you *anything*, but that is not true for $1 + \text{anything}$.

In the individual descriptions that follow, the value of a verb's identity element is noted where it has one. The identity elements are summarized in Figure 5-2. (See also the discussion of the \nearrow and \nwarrow adverbs in Chapter 6, "Adverbs and Conjunctions".)

Dyad	Identity Element	Dyad	Identity Element
+	0	•	None
-	0		0
×	1	!	1

≤	1	⌊	Largest representable number 7.2370055773322621e75
≡	1		

Figure 5-2: Identity elements for scalar dyads.

Result Rank and Shape

For many verbs, a result cell has the same rank and shape as its argument cells. Wherever the rank or shape of a result cell is different from the rank or shape of the argument cells, the description notes that fact.

Verb Definitions

$+$ $-$ \times \div

Plus, Minus, Times, Divide

These four dyads are familiar from elementary arithmetic. The monads are also defined, and given names as follows:

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
$+$	Conjugate	Plus	0	0 0 0
$-$	Minus; Negate	Minus	0	0 0 0
\times	Signum	Times	1	0 0 0
\div	Reciprocal	Divide	1	0 0 0

Dyads $+$ $-$ \times \div

The dyadic meanings are those of arithmetic.

For complex arguments, the usual rules apply. That is, the sum (or difference) of a pair of complex numbers is the sum (or difference) of their real and imaginary parts considered separately:

```
2j4 + 1.5j2.1
3.5j6.1
```

The fact that the sum of two complex numbers is represented by the sum of their real and complex coordinates taken separately is something you can exploit in graphics applications. Using complex numbers to describe a set of points in a plane, you can compute a linear translation of a set of points simply by using $+$ to add the amount of change in the two axes.

Cartesian Representation of Complex Product

The product of a pair of complex numbers can be stated in terms of operations on their Cartesian representations. Suppose a verb *Ct* decomposes a complex number into its real and complex parts, and the inverse *Cx* re-constructs a complex value from such a representation. Then the product of two complex numbers α and ω is given by the following definition of *Times*:¹

¹ These definitions are shown in a compact style called *direct definition*. Each verb's definition takes a single line. The verb's name is to the left of the colon. Its left argument is represented by α and its right argument by ω . The result of the sentence is the verb's result. For more detailed treatment of this form of definition, see "A Dictionary of APL," Table 3, p. 39.

```
Times: Cx (-/axw), 0 (+/axw) → α+Ct α → ω+Ct ω
Ct:  9 11 0 1 0 ω
Cx:  +/ 9 11 0 1  ω
```

The complex value is the real part plus i times the complex part, where $i = \sqrt{-1} \approx 0.5$. The expression $+/-9 \ 110$ achieves that because $-90w$ is defined to be ω , while $-110w$ is defined to be i times ω .)

Polar Representation of Complex Product

The product can also be computed when each complex number is represented by its magnitude and phase angle. In that case, the product of two of them has:

- magnitude equal to the product of their magnitudes
- phase equal to the sum of their phases.

Suppose that a verb *MP* decomposes a complex number into its magnitude and phase angle, and the inverse *CMP* reconstructs a complex value from such a representation. Then the product of two complex numbers α and ω is given by the definition of *Times*:

```
Times: CMP (1 0/axw), 0 1/α+ω → α+MP α → ω+MP ω
MP:  10 12 0 1 0 ω
CMP:  x/ 10 12 0 1  ω
```

Rotation of a set of points in the complex plane through an angle of θ radians is equivalent to multiplying by a number having magnitude 1 and phase θ ; you can exploit this identity in graphics applications that use complex numbers to describe a set of points in a plane.

Division by Zero

As in arithmetic, dividing a non-zero quantity by zero is undefined and the interpreter rejects it as a domain error. However, to preserve some convenient identities, APL defines $0 \div 0$ to be 1.²

Monad +

$+w$ gives the conjugate of w , also called the complex conjugate. Formally:

$$\begin{aligned} +w &\iff (|w/w) + w && \text{When } w \neq 0 \\ +w &\iff 0 && \text{When } w = 0 \end{aligned}$$

²"A Dictionary of APL" follows McDonnell's argument that $0 \div 0$ should be 0 ("Zero Divided by Zero," *ACM Quote-Quad*, APL76, pp. 295-307). However, the convention that $0 \div 0$ is 1 was adopted by all early implementations of APL, and is included in the ISO standard for APL.

The conjugate is the value you get when you reflect the argument around the real axis. The real part is unchanged, but the sign of the imaginary part is reversed. For example:

$$\begin{array}{r} +9 \ 7j3 \ -7j2 \ 8j^{-3} \ -2j^{-3} \\ 9 \ 7j^{-3} \ -7j^{-2} \ 8j3 \ -2j3 \end{array}$$

Thus, $+\omega$ differs from ω only when ω is complex.

Monad -

The result has the same magnitude as the argument, but opposite sign. For a complex argument, the result reverses the signs of both the real and the imaginary part.

Monad ×

$\times\omega$ gives the *trend* of ω . For real arguments, that is equivalent to the *signum*; the result is:

- 1 where ω is positive;
- 0 where ω is 0;
- 1 where ω is negative.

Formally, the trend is defined by:

$$\begin{array}{ll} \times\omega \iff \omega \div |\omega| & \text{When } \omega \neq 0 \\ \times\omega \iff 0 & \text{When } \omega = 0 \end{array}$$

For a complex argument, the result is the point at which a ray from the origin to ω intersects the unit circle.

The trend is *not* affected by $\square\epsilon z$, comparison tolerance. See the definition of equal (\equiv) for a definition of tolerant comparison.

Monad +

$+\omega$ is defined as $1 \div \omega$, that is, as *reciprocal*. As in arithmetic, reciprocal is undefined when the argument is 0, so you get a domain error.

Matrix Inverse; Matrix Divide

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
	Matrix inverse	Matrix division	[none]	2 oo 2

The verb *domino* is a generalization of the mathematical function *matrix inverse*. Mathematicians have no special symbol for matrix inverse, but indicate it by writing M^{-1} . Matrix inverse is analogous to the reciprocal because, just as (for a non-zero number n)

$$1 \iff (\div n) \times n$$

for a non-singular matrix M

$$I \iff (\img alt="Matrix inverse symbol"/> M) +. \times M$$

where I is the *identity matrix* (a square matrix having the same number of columns as M , with ones along the diagonal and zeros elsewhere) and $+. \times$ is the *matrix dot-product*, an analog of multiplication for matrices.²

Just as not all numbers have a reciprocal (zero has no reciprocal), not all matrices have inverses. Matrices with no inverse are called *singular matrices*.

Continuing the analogy with division of numbers, matrix division satisfies the identity (for two appropriately shaped matrices A and M , and M not singular).

$$\begin{array}{ll} a \iff (a \div n) \times n & \text{(Numbers)} \\ A \iff (A \img alt="Matrix inverse symbol"/> M) +. \times M & \text{(Matrices)} \end{array}$$

If you attempt to use a singular matrix as the right argument to , APL rejects the expression as a *domain error*.

Monad

The inverse of a non-singular matrix M is found by M . The monadic use M is equivalent to $I \img alt="Matrix inverse symbol"/> M$. The shape of each result cell is the reverse of the shape of an argument cell.

Dyad

In general, the matrix quotient $a \img alt="Matrix inverse symbol"/> b$ is linked to the inverse of a matrix by the identity:

² See the discussion of *inner product* in the section on the *dot* (.) conjunction in Chapter 6, "Adverbs and Conjunctions".

$$\alpha \mathbb{B} \omega \iff (\mathbb{B} \omega) +. \times \alpha$$

When ω is square (that is, has as many rows as columns), the solution is exact. When ω has more rows than columns, the result is the least-squares approximation that minimizes the sums (down the columns) of the squares of the difference between α and $\omega +. \times \alpha \mathbb{B} \omega$.

For a matrix M and column-vector (that is, a one-column matrix) c having the same number of rows as M ,

$$c \mathbb{B} M$$

is the solution to a set of linear equations:

c The constant terms.

M A matrix containing the coefficients for each of the unknowns.

M has a column for each unknown, and a row for each equation. Since you must have at least as many equations as unknowns, M must have at least as many rows as it has columns. When M is square, and has the same number of rows as c , then:

$$c \equiv M +. \times c \mathbb{B} M$$

When M has more rows than columns (and there is a row of M for each major cell of c) then $c \mathbb{B} M$ is the least-squares approximation, defined to minimize each of the column-sums

$$+/\mathbf{d} \times \mathbf{d} \leftarrow \mathbf{d} + c - M +. \times c \mathbb{B} M$$

where \mathbf{d} is the difference between c and $M +. \times c \mathbb{B} M$. When the solutions are real, $\mathbf{d} \times \mathbf{d}$ is equivalent to $\mathbf{d} \div 2$.

APL treats a rank-1 left argument as if it were a one-column matrix. (See the discussion of "Frame and Cells with Dyad \mathbb{B} ", below.)

Example: Multiple linear regression requires a list of dependent observations in the column-vector c and a matrix of independent or *predictor* observations p . The matrix p has a column for each of the independent variables and a row for each row of c . (Since APL accepts a list in the place of a column vector, that may be an item of c for each row of p .) The coefficients of the best-fitting linear combination of the independent variables are obtained from $c \mathbb{B} p$.

Example: Finding a best-fitting polynomial is essentially the same procedure but with a single independent variable. The columns consist of the list of observations of that variable, each raised to the successive powers by an expression. Hence, to find the coefficients of the best-fitting polynomial of

degree d to approximate the observations α from a predictor variable p , the expression is: ¹

$$\alpha \equiv p \circ + 0, 1 d$$

When α has multiple columns, the result is a matrix containing in each of its columns an independent solution for each of the columns of α .

Frame and Cells with Dyad \equiv

The left argument of matrix division has *unbounded rank*. That is, the left argument is treated as a single cell, regardless of the number of axes. The right argument rank is 2. Thus, when the right argument has more than two axes, any additional axes constitute the frame in which the rank-2 cells are embedded. Each of the ω -cells is paired with the single cell formed by the entire α .

The length of the first axis of α must match the length of the first axis of each ω -cell. Those matching axes disappear from the result, as they do in reductions. The remaining axes of α after the first – call them α 's *trailing axes* – contain the constant terms for independent sets of equations to be solved, each set in a column of α . There is a result vector corresponding to each of α 's column vectors.

The various columns of α do not interact. Suppose each of the ω -cells has r rows. Then the first axis of α must have length r to match. Each of the columns of α , however arranged, contains a separate set of constants for which a separate solution will be found. For example, if there are six such columns, it makes no difference to the calculation whether they are arranged so that α has shape $(r, 6)$, or $(r, 6 1)$, or $(r, 2 3)$, or $(r, 3 2)$, and so on. The manner in which the axes of the arguments α and ω contribute to the axes of the result are summarized in Figure 5-3.

¹To preserve the conventional order of coefficients, with the high-order term first and the constant last, the order may be reversed, making the expression $\alpha \equiv p \circ +, \omega \circ 0, 1 d$.

Figure 5-3: Shape of the argument and result of dyad

★ ⊕

Power, Log

	Monad	Dyad	Identity Element	Argument Rank
★	Exponential	Power; Involution	1	0 0 0
●	Natural log	Log base- e	None	0 0 0

Monads ★ and ●

The *exponential* denoted by ★ w is equivalent to e^w , where e is the base of the natural logarithms, given approximately by:

★1
2.718281828

The *natural logarithm* ● is inverse to ★ in the sense that

$$w \iff \bullet \star w \iff \star \bullet w$$

Moreover, if e is e , the base of the natural logarithms $e \star 1$,

$$\bullet e \iff e \bullet w.$$

For both real and complex arguments (except when ω is 0), the log of ω is equal to the log of the absolute value of ω plus i times the phase of ω ; that is:

$$\log \omega \iff (\log |\omega|) + 0j1 \times 120\omega$$

However, for a positive real argument, $0j1 \times 120\omega$ is zero, and so has no effect on the result. For a negative real argument, the imaginary part of the result is π radians. That is because the log is equal to the arc of ω , and the arc of any negative number is π radians. $\log 0$ is undefined and results in a domain error.

```

Dyad *

The expression $\alpha \star \omega$ is often read as " α to the power ω ." $\alpha \star 2$ and $\alpha \star 3$ and $\alpha \star 0.5$ are respectively the square, cube, and square root of α . The general definition of $\alpha \star \omega$, for real and complex arguments, is:

$$\begin{aligned} \alpha \star \omega &\iff \exp(\omega \log \alpha) && \text{When } \alpha \neq 0 \\ \alpha \star \omega &\iff 0 && \text{When } \alpha = 0 \text{ and } \omega \neq 0 \\ \alpha \star \omega &\iff 1 && \text{When } \alpha = 0 \text{ and } \omega = 0 \end{aligned}$$

For the simple case of a non-negative integer right argument, $\alpha \star \omega$ is equivalent to $\times/\omega \rho \alpha$. Since $\times/$ applied to an empty list yields 1, $\alpha \star 0$ is 1 for any α , even when α is zero.

Raising a number to a fractional power is equivalent to extracting a root; for instance, the three-fifths root of α can be written $\alpha \star 3 \div 5$ or the square root of α as $\alpha \star 2$.

When α is negative and ω is fractional, the result is complex. Multiple roots may exist, some real and some complex. The result is the *first* root (proceeding counterclockwise from the positive real axis), regardless of whether it lies on the real axis. For odd integral roots, this result may sometimes be surprising. For example, although -2 is a cube root of -8 , it is not the principal root by the rule just stated:

```
      -8*+3
1j1.732050807568877
      1j1.732050807568877 ^2 *3
-8 -8
```

Dyad \circ

The base- b logarithm $b\omega$ is inverse to power in the sense that:

$$\omega \iff b\circ b\omega \iff b*b\omega$$

The dyadic logarithm $\alpha\omega$ is equivalent to the ratio of the logs of the arguments considered separately; that is:

$$\alpha\omega \iff (\alpha\omega)+\alpha$$

Since the logarithm of 1 to any base is 0, 1ω is normally a domain error and $\alpha 1$ is normally 0. But $1\circ 1$ is 1 since in APL $0\div 0$ is defined to be 1. If either of α or ω is negative, the logarithm may be complex:

```
      \omega=.0\omega+^2 2 10,01
      1 0.04642j^-0.21039 0.076663j^-0.34746
      1j4.5324              1              1.6515
0.60551j2.7444            0.60551              1
```

○ Circle Verbs

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
○	π Times	Trigonometric Functions	[none]	0 0 0

Monad ○

The expression $\omega\omega$ is equivalent to π times ω , where π is the ratio of the circumference of a circle to its diameter, approximately:

○1
3.1415926535

Dyad ○

In the expression $\alpha\omega\omega$, the left argument α must be an integer from the set -12 through 12 , inclusive. The value of α selects one of the families of circular verbs, as follows.

$\alpha \in 1 \ 2 \ 3$ Circular or trigonometric (argument in radians)
 $\alpha \in -1 \ -2 \ -3$ Inverse circular or trigonometric (result in radians)

$\alpha \in 5 \ 6 \ 7$ Hyperbolic
 $\alpha \in -5 \ -6 \ -7$ Inverse hyperbolic

$\alpha \in 0 \ 4 \ -4 \ 8 \ -8$ Pythagorean

$\alpha \in 9 \ 11$ Complex (Cartesian coordinates)
 $\alpha \in -9 \ -11$ Inverse Cartesian

$\alpha \in 10 \ 12$ Complex (polar; arc in radians)
 $\alpha \in -10 \ -12$ Inverse polar

Selection of Function by Left Argument of o

00w	$(1-w*2)*0.5$		
10w	$\sin w$	-10w	$\arcsin w$
20w	$\cos w$	-20w	$\arccos w$
30w	$\tan w$	-30w	$\arctan w$
40w	$(1+w*2)*0.5$	-40w	$w*(1-w*2)*0.5$
50w	$\sinh w$	-50w	$\operatorname{arsinh} w$

70w	$\tanh w$	-70w	$\operatorname{artanh} w$
80w	$(-1-w*2)*0.5$	-80w	$-(-1-w*2)*0.5$
90w	Real part: $(w+iw)+2$	-90w	Identity
100w	Magnitude: $ w $	-100w	$+w$
110w	Imaginary: $(w-iw)+0j2$	-110w	$0j1 \times w$
120w	Phase angle: 1100w	-120w	$*0j1 \times w$

Geometric View of the Pythagorean and Circular Functions

The various circle verbs can be represented by constructions on a unit circle whose origin is *O* (see Figure S-4). The distance *OP* is 1. The angle *a* establishes the point *P* at which a ray through the origin cuts the unit circle. For the angle *a*, the altitude *PR* represents the sine of *a*, *OR* the cosine of *a*, and *PT* the tangent of *a*.

$OP = 1$	PR sine a
$PR = \sin a$	OR cosine a
$OR = \cos a$	PT tangent a
$OT = \sec a$	PS cotangent a
$PT = \tan a$	OT secant a
$OS = \csc a$	OS cosecant a

Figure 5-4: Pythagorean and circular verbs in terms of the unit circle.

The inverse functions ~ 10 and ~ 20 have domains restricted to values whose magnitude does not exceed 1. Since sine and cosine are cyclic, a given sine or cosine is related to any of an infinite number of arcs, differing from each other by successive multiples of 2π . For a given sine, ~ 10 returns the arc lying at or between the range $-\frac{\pi}{2}$ and $\frac{\pi}{2}$ radians.

Geometric View of the Hyperbolic Functions

Figure 5-5 extends the geometric constructions shown in the preceding figure. Here again O marks the origin, the center of a unit circle, so that the distance OP is 1. The two arms of the unit hyperbola are shown tangent to the unit circle, with the major axis of the hyperbola along the horizontal axis of the figure. As before, the line SPT is tangent to the unit circle.

The hyperbolic cosine relates the coordinates of a point on the unit hyperbola to the sum of the two areas (shaded in Figure 5-5) each bounded by the following three curves:

- A line from the origin to that point.

- The unit hyperbola itself.
- The major axis of the unit hyperbola. In the figure, Q is such a point. If (as shown here) the unit hyperbola is oriented so that its major axis lies horizontally, the hyperbolic sine is the vertical distance from the origin to Q (equal to TQ). The hyperbolic cosine is the horizontal distance OQ . The hyperbolic tangent (by analogy with the circular tangent) is the ratio of the hyperbolic sine to the hyperbolic cosine.

Figure 5-5: Hyperbolic verbs in terms of the unit hyperbola.

RP = 10a sine	TQ = 50b hyperbolic sine
OR = 20a cosine	OT = 60b hyperbolic cosine
PT = 30a tangent	VW = 70b hyperbolic tangent
OS = +10a cosecant	PS = +50b hyperbolic cosecant
OT = +20a secant	QR = +60b hyperbolic secant
PS = +30a cotangent	UV = +70b hyperbolic cotangent
	b = "5030a " Gudermannian"

The inverse hyperbolic functions are *arsinh*, *arcosh*, and *artanh*. The "ar" prefix indicates "area" (whereas the prefix "arc" used with the inverse circular functions indicates "arc").

The inverse hyperbolic functions give you twice the area of the hyperbolic sector described by the corresponding *sinh*, *cosh*, or *tanh*. If x is a value of the hyperbolic sine and y is the value of the corresponding hyperbolic cosine, and z is their ratio, then the area enclosed is equal to:

$$^50x \text{ which equals } ^60y \text{ which equals } ^70z$$

The result returned for the area of the hyperbolic sine and cosine has the same sign as its argument. Since in principle *sinh* and *cosh* can take on any values, both the domain and the range of *arsinh* and *arcosh* are infinite. Since *sinh* must always be less than the corresponding value of *cosh*, *tanh* has a magnitude that approaches but can never reach 1.

In practice, the areas of the hyperbolic functions are evaluated by exploiting the following identities:

$$^50w \iff 2w + 40w$$

$$^60w \iff 2w + ^70w$$

$$^70w \iff 0.5 \times (1+w) + (1-w)$$

This method of computation gives 50 and 60 an effective domain of all numbers whose magnitude is less than about 10^{27} ; the results have magnitudes less than about 85. The *artanh* function 70 has an effective domain of numbers whose magnitude is less than about 18.

Representations of Complex Numbers

A complex number may be resolved to its real and imaginary parts by the expression $9 \ 11 \ 0.0 \ w$; for example:

$$9 \ 11 \ 0.03j4$$

$$3 \ 4$$

Or, it may be resolved into its magnitude and phase by $10 \ 12 \circ .0\omega$; for example:

```
10 12 * .03j4
5 0.927295218
```

You get the inverse transformations by exploiting the identities:

$$\omega \leftrightarrow 10^{-9} 11 + .0 \ 9 \ 11 \circ .0 \ \omega$$

$$\omega \leftrightarrow 10^{-10} 12 \times .0 \ 10 \ 12 \circ .0 \ \omega$$

(See also the discussion of complex arguments accompanying the descriptions of $+$ $-$ \times $+$.)

⌈ ⌊

Floor, Ceiling; Max, Min

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
⌈	Ceiling	Maximum	$-\infty$	0 0 0
⌊	Floor	Minimum	∞	0 0 0

Monads \lfloor and \lceil

The expression $\lfloor \omega$ returns the *floor* or *integer part* of ω . When ω is an integer, the result is ω ; but when ω has a fractional part, the result is the first integer that is smaller than ω . Stating it the other way, $\lfloor \omega$ is the largest integer that is not greater than ω .

```
⌊3.1 0 -6.7 -9
3 0 -7 -9
```

The expression $\lceil \omega$ returns the *ceiling* of ω . When ω is an integer, the result is ω ; but when ω has a fractional part, the result is the next larger integer. Thus, $\lceil \omega$ is the smallest integer that is not smaller than ω .

```
⌈3.1 0 -6.7 -9
4 0 -6 -9
```

$\lceil \omega$ can be defined in terms of $\lfloor \omega$ thus:

$$\lceil \omega \leftrightarrow \lfloor -\omega \leftrightarrow -\lfloor -\omega$$

Tolerant Floor and Ceiling

The implied comparison of w with the integers is *tolerant*. When w is sufficiently close to an integer, both $\lceil w$ and $\lfloor w$ are w . "Sufficiently close" is defined in terms of the visible value of the system variable $\square ct$. The formal definitions of floor and ceiling are:⁴

$$floor: n - (\square ct \times 1 \uparrow |w|) < ((n + (xw) \times |0.5 + |w|) - w$$

$$ceiling: -floor - w$$

Thus, if x is any integer $\square ct$, the ceiling of x is that integer, even though in that case $\lceil x$ is (strictly speaking) smaller than x .

The default value of $\square ct$ is $1.4196976927394189e^{-14}$.

Floor of a Complex Number

You can represent a complex number as a geometrical point in the complex plane: a plane in which displacement along the x-axis represents the real portion and displacement along the y-axis represents the imaginary portion of a number. The floor of a complex number lies at a point on the intersection of lines for real and imaginary integers; that is, both its real and its imaginary parts are integers. You can think of the process of finding the floor as motion from a point anywhere in the complex plane to a point at one of the vertices of the surrounding square bounded by the real and imaginary integer lines (see Figure 5-6).

The vertex chosen is one that satisfies the constraint that the distance between a number and its floor is always less than 1. Thus, there is a zone in each square for which the floor is *not* what you would get by taking the floors of the real and imaginary parts separately.⁵ The algorithm by which APL finds the floor of a complex number is the one proposed by McDonnell in 1973.⁷ Imagine a grid of integer lines on the complex plane. The task is to map a point anywhere in the plane to one of the lattice points on the grid — that is, to a point whose coordinates are described by a real integer and an imaginary integer. The floor f of a complex number w is found by the following algorithm.

- Let LL be the point at the lower left corner of the unit square containing w .

⁴These were derived by Robert Barnocky and D.L. Fortes in 1978. See *SHARP APL Technical Note 23: Comparison Tolerance*, I.P. Sharp Associates, 1978.

⁵An application that requires complex floor calculated in that way can obtain it by `"9 "11+.019 12+.001`.

⁷Eugene E. McDonnell, *Integer functions of complex numbers with applications*, IBM Scientific Center Technical Report No. 320-3015, 1973. Summarized as: Eugene E. McDonnell, "Complex Floor," in Per Ojertqvist, ed., *APL Congress 1973*, North Holland Publishing, 1973.

- Let fr and fi be the fractional parts of the real and imaginary parts of w .

Then,

When $1 > fr + fi$: $f \leftarrow LL$

When $(1 \leq fr + fi)$ and $fr \geq fi$: $f \leftarrow LL + 1$

When $(1 \leq fr + fi)$ and $fr < fi$: $f \leftarrow LL + 0j1$

Those rules can be stated as APL direct definitions in which L and $|$ are applied only to real arguments:

```
floor: (LL w) + ((case1 w), (case2 w), case3 w) / 0 0j1 1
LL: (1|real w) + 0j1 * 1|imag w
case1: 1 > (fr w) + fi w
case2: (1 ≤ (fr w) + fi w) ∧ (fr w) < fi w
case3: (1 ≤ (fr w) + fi w) ∧ (fr w) ≥ fi w
fr: 1|real w
fi: 1|imag w
real: 90w
imag: 110w
```

Figure 5-6: Mapping of points in a unit square to complex integers.

In Figure 5-6, a unit square is divided by its diagonals into four zones. A point in Zone 1 or Zone 2 is mapped to LL ; a point in Zone 3 to $LL+0j1$, and a point in Zone 4 to $LL+1$.

The zone of all points in the plane that are mapped to a particular complex integer is thus a rectangle tilted at 45° , with the floor at the center of its lower edge. Figure 5-7 shows a portion of the complex plane tiled by such rectangles.

Figure 5-7: The complex plane tiled by areas having equal floors.

Dyads \lfloor and \lceil

$\alpha\lfloor\omega$ returns the minimum of α and ω (that is, whichever is smaller), and $\alpha\lceil\omega$ returns the maximum (that is, whichever is greater). For example:

```
3 4 ⍷ 4
3 4
```

Maximum and minimum are not tolerant; that is, their results are not subject to `0ct`. These verbs are defined only for real arguments; the system reports a *domain error* when an argument is complex or non-numeric.

When the reduction adverb \wedge modifies \uparrow , the result is the maximum of the major cells of ω . For example, if the shape of x is 3 4 5, then

$$\uparrow x \iff x[1;:] \uparrow x[2;:] \uparrow x[3;:]$$

When the first axis of ω has length zero, the result is the identity element for maximum. That is the number compared to which all other numbers are bigger: minus infinity. In practice, the APL system returns the smallest representable value. The actual value depends on the particular system. In APL, it is approximately equal to -7.237×10^{76} .

For the same reason, the identity element for \downarrow is positive infinity, and the system returns the largest number it can represent. Here too, the actual value depends on the particular system. In APL, it is approximately 7.237×10^{76} .

Magnitude; Residue

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
	Magnitude; Absolute value	Residue	0	0 0 0

Monad |

The definition $|\omega \iff (\omega\bar{\omega}) \div 0.5$ yields the *magnitude* or *absolute value* of ω . This definition applies equally to real and to complex arguments. For a complex ω , the result is the hypotenuse of a right triangle whose sides are the real and imaginary parts of the number. If the real and imaginary parts of ω are denoted as re and im , then $|\omega$ is $((re^2) + (im^2)) \div 0.5$.

Dyad |

A familiar use of residue is to determine the remainder resulting from dividing a non-negative integer by a positive integer. For example:

```
3|0 1 2 3 4 5 6 7 8.1
0 1 2 0 1 2 0 1 2.1
```

The definition $\alpha|\omega \iff \omega - \alpha \times \lfloor \omega \div \alpha \rfloor$ extends this notion to a zero left argument. When α is zero, the result is the right argument unchanged. It also extends the verb's domain to fractional right arguments and to negative or fractional left arguments. When α is a negative integer, the result ranges between α and zero, just as it does when α is positive. For example:

```

      3|4 3 2 1 0 1 2 3 4
-1 0 2 1 0 2 1 0 2

```

```

      1|2.5 3.64 2 1.6
0.5 0.64 0 0.4

```

However, for cases such as $(+3)|2+3$, in order to produce a true zero (rather than a small fraction) the residue is made *tolerant* in the following way. Where α is non-zero, and ω is not an integer multiple of α , the residue is found by subtracting from ω the product $\alpha \times S$, where S is the tolerant floor of ω/α . Stating the same thing more formally:

Let $S = \omega/\alpha + \alpha \approx 0$
 When $(\alpha \neq 0) \wedge (\lceil S \rceil \neq S)$, $\alpha | \omega \iff \omega - \alpha \times \lceil S \rceil$
 Otherwise, $\alpha | \omega \iff \omega \times \alpha \approx 0$

For example:

```

      0.1|2.5 3.64 2 1.6
0 0.04 0 0

```

Consider the result when the modulus is 3 or ~ 3 and the right argument is 10 or ~ 8 :

```

      3 3 .|. 10 8
1 1
2 2

```

Figure 5-8 illustrates the results obtained from the above example.

The definition of residue applies equally to complex arguments. The extension takes advantage of the properties of \lfloor (floor) applied to complex arguments. As a consequence, the residue of any number (whether real or complex) is always less in magnitude than the modulus (except for the special case of zero modulus, when the residue has the same value as the right argument).

For example, when $\square ct$ is set to 0, because of imprecisions in the internal representation, the following expression misses certain multiples:

```

      0.24j-.32|15 -□ct=0
0.12j-0.16 0.32j0.24 0.12j-0.16 0.32j0.24 0.12j-0.16

```

But with the default value of $\square ct$, APL is able (correctly) to detect that 2 and 4 are multiples of $.24j⁻.32$ and to return a 0 residue:

Figure 5-8: Schematic representation of $3^{-3}|10$ and $3^{-3}|^{-8}$.

```

)clear
clear ws
0.24j^-0.32 |15
0.12j^-0.16 0 0.12j^-0.16 0 0.12j^-0.16

```

!

Factorial; Combinations

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
1	Factorial; Gamma	Out of; Combinations; Binomial coefficients	1	0 0 0

Monad !

When ω is a non-negative integer, the factorial is defined by:

$$!\omega \iff \pi / \Gamma \omega$$

For example, 14 is $\pi / 1 \ 2 \ 3 \ 4$, or 24, and 10 is 1.

For a negative integer, the factorial is undefined. For a real argument other than a non-negative integer, $!w$ is closely related to the gamma Γ function,⁸ so that a value of the gamma function can be obtained from:

$$\Gamma(w) \Leftarrow !w-1$$

Dyad :

The dyad $\alpha ! w$ is defined in terms of the monad thus:

$$\alpha ! w \Leftarrow (!w) + (!\alpha) \times (!w - \alpha)$$

For non-negative integer arguments, $\alpha ! w$ yields the number of distinct ways of selecting α things from w things; this accounts for the name "out of," and for its use in producing binomial coefficients. For example:

```

      0 1 2 3 4 4
1 4 6 4 1

```

For a negative integer I , the expression $!I$ is not defined, because, near a negative integer, the magnitude of $!I$ approaches infinity. In the definition of $\alpha ! w$ shown above, these near-infinities may cancel, permitting $\alpha ! w$ to be evaluated provided we assume that these infinite values occur in the following ways:

1. When α and w are both non-negative, but $\alpha > w$, the term $!w - \alpha$ is infinite, yielding 0 for the result of $\alpha ! w$. This agrees with the observation that there are no ways to pick α things from a smaller collection.
2. When infinite values occur in both numerator and denominator, they are assumed to cancel. This can be seen in the values in the following function table:

	$!-3$	$!-2$	$!-1$	$!0$	$!1$	$!2$	$!3$
$!-3$							
$!-2$	1						
$!-1$	0	1					
$!0$	0	0	1				
$!1$	1	1	1	1			
$!2$	-3	-2	-1	0	1	2	3
$!3$	6	3	1	0	0	1	3
$!4$	-10	-4	-1	0	0	0	1

⁸ The gamma function (and also the beta function B , mentioned on the next page) are outside the scope of this manual. See a standard mathematical reference, for example *Handbook of Mathematical Functions*, US Department of Commerce, National Bureau of Standards, Applied Mathematics Series #55.

The generalized definition adopted for dyad \uparrow permits evaluation of the Beta function by the identity:

$$B(\alpha, \omega) \iff +\omega \times (\alpha - 1) : \alpha + \omega - 1$$

?

Roll; Deal

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
?	Roll	Deal	[none]	0 * *

The *random* verb ? selects either a single number or a set of distinct numbers from a population of numbers. For example, each of the following selects from the first ten integers:

```

?10
4

3?10
9 2 7
```

The size of the population from which numbers are selected is determined by the value of the right argument. The population is the first ω integers; that is, a result cell is selected from 1ω . The population is therefore affected by the value of $\square 10$.

Monad ?

The verb *roll* is named from the analogy with rolling a die to choose one of a set of numbers with equal probability.

Dyad ?

The verb *deal* is named by analogy with dealing from a pack of cards. The result of $\alpha ? \omega$ for each of the corresponding cells of α and ω is a list of length α in which all the elements are distinct.

Argument Rank

The default rank of dyad ? is at present undefined; ? may be used with array arguments only by stating its argument rank explicitly. For example, to independently generate four random numbers taken from 1100 and also four taken from 1200 :

```

      4 ?0 100 200
56 27 84 20
20 116 133 180

```

Pseudo-random Algorithm and $\Omega r1$

The results of $?$ (both monad and dyad) are "pseudo-random." That is, although the results (collectively) satisfy most tests of randomness, they are produced by an explicit and repeatable algorithm. The value returned depends on the visible value of the system noun $\Omega r1$ (*random link*). Each time APL (successfully) executes $?$, it sets $\Omega r1$ to a new value. If, on different occasions, you set the same value of $\Omega r1$ and then invoke $?$ on the same arguments in the same sequence, you get the same results. (See the discussion of $\Omega r1$ in Chapter 11, "System Nouns and Verbs".)

The algorithm for generating random numbers is the *Linear Congruential Method* developed by D.H. Lehmer in 1951.⁶ The algorithm depends on two constants: a prime $p=2147483647$ and a multiplier $m=16807$. (The prime is the largest prime representable with 31 binary digits. The multiplier is a primitive root of p that is close to the square root of p ; the value 16807 is $7*5$.)

When ω is an item less than 2^{31} , APL finds the value of $? \omega$ by

$$? \omega \Leftarrow \lfloor \omega + (\omega \Omega r1 + p) \div (\Omega r1 + p) m \Omega r1$$

in which \lfloor means the non-tolerant floor (as one would get when $\Omega c t$ is 0).

For an argument greater than or equal to 2^{31} , APL sets $\Omega r1$ twice. If the result of the intermediate set is called $r1$, so that

$$\Omega r1 + p \times r1 + p \div m \Omega r1$$

the formula becomes

$$? \omega \Leftarrow \lfloor \omega + m((r1 + \Omega r1 \times 2 + 32) + 16 + 8) \div 2^{31} + 2 \times 31$$

Random numbers generated in this fashion are rectangularly (or "uniformly") distributed; you can get other distributions by applying various transformations to the rectangular values that $?$ generates. For example, random normal deviates with mean=0 and $\sigma=1$ may be obtained by:

$$\begin{aligned} \text{normal} &: (1002 \times \text{uniform } \omega) \times (\sqrt{2} \times \text{uniform } \omega) \times 0.5 \\ \text{uniform} &: (? \omega p m - 1) \div m - 2147483647 \div \Omega c t - 1 \end{aligned}$$

APL evaluates $? \omega$ using repeated calls to a short cut version of the mechanism for monad $?$. In principle, the method is to generate random integers,

⁶ See D.E. Knuth, *The Art of Computer Programming - Seminal Algorithms*, Vol. 2, Addison-Wesley, 1969.

keeping those that fall within the range specified by α and discarding those that do not. However, the result of dyad ρ is not necessarily what you would get by using monad ρ and discarding out-of-range items from the result.

< > >

Box, Open; Link

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
<	Box; Enclose	[see Less]	[none]	∞ 0 0
>	Open; Disclose	[see Greater]	[none]	0 0 0
>	Conditional box	Link	[none]	∞ ∞ ∞

The monads < and > form a box and open a box, respectively. (The dyads < and > are the relations *less* and *greater*, discussed in the next section.)

A box is an item (or scalar). It has no axes. However, it may contain an array of any type, rank, or shape. A box is thus a scalar encoding of an array.

Because a box is an item, within an array of boxes each individual box occupies a single position, just as a number occupies a single position in a numeric array, or a character in an array of characters. An array of boxes thus permits you to handle nouns of arbitrary rank and shape within the same simple rectangular framework used for numbers or characters.

Boxing an array always produces a result that is an item and always increases by 1 the number of times it will be necessary to open the item to retrieve its unboxed contents. This is made obvious when you set $\Omega\rho s$ so that the boundaries of a box are shown explicitly in its display. For example:

```

       $\Omega\rho s \leftarrow 0$  0 2 2
       $\vdash x \leftarrow 126$ 
126                                     «Open item

      <x                               «One level of boxing
┌───┐
│126│
└───┘

```

Thus, when the argument ω is already an item, $\ll\omega$ boxes it again and produces a result with an additional level of boxing; $\ll\omega$ is never identical to ω .¹⁰ Thus, an open item (that is, a number or character) is not equal to any boxed item, not even to the same item enclosed in a box:

```

2 = <2
0

```

Monad >

The monad $>$ is the inverse of $<$; it opens a box, to disclose what lies within. When ω is an item, $>\omega$ returns the array that was boxed to produce ω .

When the argument ω is already open, the result is the same as the argument.

An attempt to open arrays containing mixed character and numeric data results in a *domain error*.

Since $>$ has argument-rank 0, all the axes of ω are *frame axes*. Thus, the result returned by $>\omega$ has the same axes as ω , followed by the axes of the arrays disclosed from the various boxes. When all the boxes contain cells of the same rank and shape, the cell axes returned by $>\omega$ are the axes common to all of them. For example, when ω is a 5-by-2 table of boxes and each box contains a 3-by-4-by-7 array, then the shape of $>\omega$ is 5 2 3 4 7.

When each item is boxed, items of irregular type or shape can be arranged in a regular array. Thus, *open* may be usefully modified by the *under* conjunction $\underbar{\hspace{.1em}}$, using *open* with another verb which is to be applied to each item of the boxed argument(s), such as *lengths* $\underbar{\hspace{.1em}}>$ *pieces*.

Tolerant Open

When the arrays contained in the various boxes are of the same type, but differ in rank or shape, each result is "padded" as necessary so that every

¹⁰ In this regard, the rules for boxing in APL differ from those governing the analogous verb in APL2. APL2 does not permit an item to be boxed, but returns the same item unchanged. Since APL2 restricts boxing to arrays whose rank is greater than 0, in order to have items and boxes in the same array, APL2 requires *mixed arrays*, in which the higher-rank *enclosed* and *boxed* items are boxed and boxed.

cell in the result has the same rank and shape. In this sense, *open* is said to be *tolerant*, since it does not require the various arrays to have the same shape. Each is given a rank equal to the maximum rank boxed within ω by logically concatenating leading 1s to its shape vector. Each axis is given a length equal to the maximum length that that axis has in any of the boxes in ω :

```

      ⍵←"1∘<' The quick brown fox.'
      |-----|
      |The|quick|brown|fox,|
      |_____|
      >⍵

The
quick
brown
fox,

      ⍬←⍵
      4 5

```

Fill Elements

Where the array within a box has a length less than the maximum length for that axis, the corresponding cell in the result is padded with *fill elements* – extra items to make up the needed length. A character array is padded with trailing blanks, a numeric array with 0s, and an array of boxes with the enclosed empty box <10.

Each cell of the result of $>\omega$ is expanded to have the common shape of all the result cells, as follows:

Cell – the array disclosed by opening a single box in ω
MaxRank – highest rank inside all boxes in ω
MaxShape – maximum length of the axes inside all boxes in ω

CommonShape: $\text{MaxShape} \uparrow (1 \uparrow (-\text{MaxRank}) \uparrow \rho \text{Cell}) \rho \text{Cell}$

This is illustrated in Figure 5-9.

When you use one of the composition adverbs (described in Chapter 6, "Adverbs and Conjunctions"), it is possible to combine *open* with *box* for each cell. Each box in the argument is opened, processed in some manner, and then re-boxed. In that situation, there is then no need for padding,

Figure 5-9: Shape of result cells produced by tolerant open.

because the variously-shaped intermediate results are not assembled into the result until re-boxed.¹¹

Monad \triangleright

When ω consists of boxes, the result of monad \triangleright is ω , unchanged. But when ω is open, $\triangleright\omega$ boxes it. This is why monad \triangleright is called *conditional box*.

You can use the expression $\omega\triangleright\omega$ to determine whether ω is open or boxed.

Dyad \triangleright

The dyad \triangleright (*link*) forms its arguments into an array of boxes. It always boxes α , but it boxes ω only when ω is open.

Thus, dyad \triangleright can be defined in terms of dyad join \Join , and monad \triangleright as follows:

$$\alpha \triangleright \omega \iff (\langle \alpha \rangle, \triangleright \omega)$$

¹¹ In APL, the special case expression $\alpha \triangleright \omega$ corresponds to the APL2 *each* expression $\alpha \triangleright^* \omega$.

The *conditional boxing* of the right argument lets you use a simple expression to box and join several objects without parentheses:¹²

```
Who←'Tom'>'Dick'>'Harry'
ρWho
3
```

```
Who
┌───┐┌───┐┌───┐
│Tom││Dick││Harry│
└───┘└───┘└───┘

┌─Who─┐'Jane'>Who
┌───┐┌───┐┌───┐┌───┐
│Jane││Tom││Dick││Harry│
└───┘└───┘└───┘└───┘
```

Using link with the rank conjunction lets you link one array with parts of another. Consider a compiler that generates declarations for another computer language for a list of names. If *names* is a list of boxed names, then the declarations might be generated as follows:

```
names
i
foo
vtom
squeeze
nub

'static VAR 'i' 0 names
static VAR i
static VAR foo
static VAR vtom
static VAR squeeze
static VAR nub
```

Watch out: When you need to add another box at the end of *Who* – for example, to add 'Jill' so that her name follows the other names – it is not appropriate to write:

```
Who←Who>'Jill'
```

That would put a new level of boxing around *Who*, and result in the two-item list:

¹² This achieves the principal benefit of APL2's vector or *array* notation without the syntactic complexities that APL2 introduces by allowing nouns to be linked simply by juxtaposition.

Jane	Tom	Dick	Harry	Jill	

To add one more box at the end:

`Who←Who,<'Jill'`

< >

Less; Greater

≤

Less than or Equal

≥

Greater than or Equal

	Dyad	Identity Element	Argument Rank
<	Less	0	∞ 0 0
≤	Less than or equal	1	* 0 0
≥	Greater than or equal	1	* 0 0
>	Greater	0	0 0 0

These four dyads are discussed together because they are closely related. There is no monad \leq or \geq . Monads $<$ and $>$ are *bar* and *open*, discussed in the preceding section.

A result cell returned by these propositions contains 1 where the proposition is true, and 0 otherwise. The domain is restricted to real numbers. (APL has no collating sequence for characters. Hence, comparisons such as $'a' < 'b'$ produce *domain error*.)

Each of these verbs makes *tolerant* comparisons, subject to the visible value of the system variable Ωct . To examine the effect of Ωct , let $tEqual$ be a user-defined verb whose result is 1 when a and w are equal within the limits of tolerance set by Ωct .¹³

`tEqual: 0≤(Ωct×(|a|(|w)-|a-w`

¹³ See the discussion of "tolerant comparison" in the section of "equal and unequal", which follows.

Then the following shows how the four propositions $< \leq \geq >$ are affected by `Oct` by referring to expressions in which the effect of `Oct` is confined to `tEqual`:

$$\begin{aligned} \alpha < \omega &\iff (\alpha < \omega) \wedge \sim \alpha \text{ tEqual } \omega \\ \alpha \leq \omega &\iff (\alpha < \omega) \vee \alpha \text{ tEqual } \omega \\ \alpha \geq \omega &\iff (\alpha > \omega) \vee \alpha \text{ tEqual } \omega \\ \alpha > \omega &\iff (\alpha > \omega) \wedge \sim \alpha \text{ tEqual } \omega \end{aligned}$$

$= \neq$

Nubsieve; Equal, Unequal

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
$=$	[none]	Equal	1	* 0 0
\neq	Nubsieve	Unequal	0	oo 0 0

Monad \neq

Monad \neq is defined as *nubsieve*. It produces a Boolean list that marks the nub (the unique major cells) of ω . For example, with a list argument, the unique items are found. With a table, the unique rows of the table are found, and so on:

```

      #'abacus'
1 1 0 1 1 1
      b
mabel
toto
lisa
fred
lisa
fred
dorothy
toto
mabel
fred
nancy
ed
nancy
      #b
1 1 1 1 0 0 1 0 0 0 1 1 0
      (#b)#b
mabel
toto
lisa
fred
dorothy
nancy
ed

```

The commonly used expression for the nub of a list

```
nub: ((⊆pw)=w)w)/w
```

can be written more efficiently and compactly using nub sieve as

```
nub: (pw)/w
```

Formally, nub sieve is defined on lists as:

```
ns: ⍋0 1 xpw : (<~a)∨a\ns(a+⊆1pw)/w
```

For arrays, major cells are used in place of list elements.

Since nub sieve is defined in terms of tolerant inequality, it is sensitive to Ω ct.

Dyad =

A result cell of $\alpha=\omega$ is 1 when the items compared are equal, and 0 otherwise.

No character is equal to any number; in particular:

```
123='123'  
0 0 0
```

Two characters are equal only when their internal representations are equal (that is, when they have the same position in Ω av, the set of all possible characters). For example:

```
'a'='Ananas'  
0 0 1 0 1 0
```

In a few cases, usually involving characters whose appearance differs according to national convention, a device may generate the same display for two different characters. The fact that the displays are indistinguishable does not make the characters equal.

Tolerant Comparison of Real Numbers

APL judges two numbers to be equal when the absolute difference between them is not greater than Ω ct times the greater of their magnitudes. Formally, using the non-tolerant meaning of \leq :

$$(|\alpha - \omega| \leq \Omega \text{ct} \times (|\alpha| \vee |\omega|))$$

APL limits the maximum permissible value of Ω ct. To be valid, Ω ct must be a non-negative item less than 16×10^{-8} (which is about $2.328306437 \times 10^{-10}$).¹⁴

There are two practical consequences of the way Ω ct affects comparisons and the limit on the maximum value Ω ct can be given:

- Tolerance cannot affect comparisons with zero. That is, no comparison in which one of the items is 0 can be judged equal to another unless they are exactly equal. This is true regardless of the value of Ω ct.
- Tolerant comparison can make a difference only to numbers whose internal representation requires floating point. (Stating it the other way, no matter what legal value you give Ω ct, two numbers whose internal type is *integer* can be reported "equal" only when they are exactly equal.)

¹⁴ If you give Ω ct a value outside that range, APL does not immediately object. It reports Ω ct error at the next use of a verb that implicitly refers to Ω ct.

Dyad \neq

The verb *unequal* is the negation of *equal*:

$\alpha \neq \omega \iff \sim(\alpha = \omega)$

Match

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
\equiv	[none]	Match	[none]	* * 00 00

The dyad \equiv returns a Boolean item reporting whether α is identical to ω . To be judged identical, α and ω must have:

- the same *rank*
- the same *shape*
- Throughout that shape, the same *value*.

For numeric items, the magnitude of their difference must be no greater than 10^{-6} times the greater of their magnitudes. (See the discussion of "tolerant comparison" in the description of "equal", earlier in this chapter.)

Since each item in one array must be equal to the corresponding item in the other, arrays that are not empty must necessarily be of the same type (numeric or character). However, empty arrays of the same rank and shape match regardless of type. Moreover, the internal type of a numeric array does *not* affect comparison. For example, an array stored in the integer format may match an array stored in floating format, provided, of course, that the actual values in the floating point array are equal (or sufficiently close) to those in the integer array.

Match has infinite default argument rank. That is, unless explicitly modified by the *rank* conjunction \wedge , match treats the entire argument as a single cell and returns a single 1 or 0. Modifying \equiv with the rank conjunction, you can define the cells to which it applies. For example:

$L \equiv \wedge 1 \omega$ α Compare list L with each row of ω .

$T \equiv \wedge 2 \omega$ α Compare table T with each table of ω .

Since empty arrays do not have items which can differ from one another, they match if their ranks and shapes match:

$'' \equiv 10$

1

~

Not

	<i>Monad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
~	Not	1	0 * *

The monad ~ (*not*) is defined only on *Boolean arguments*; that is, arguments whose values contain only 1 or 0. For 1 it returns 0; for 0 it returns 1. The dyadic case of ~ is undefined.

^ v * ~

LCM, GCD; And, Or; Nand, Nor

	<i>Numeric Arguments</i>	<i>Boolean Arguments</i>	<i>Identity Element</i>	<i>Argument Rank</i>
^	LCM	And	1	* 0 0
v	GCD	Or	0	* 0 0
*	[undefined]	Nand	[none]	* 0 0
~	[undefined]	Nor	[none]	* 0 0

Boolean Arguments

For Boolean arguments (0 and 1), the v is equivalent to the logical *or*, and the ^ to logical *and*. Thus:

```

p←0 1
p *.^ p
0 0
0 1

p *.v p
0 1
1 1

```

The verbs * and ~ (called *nand* and *nor*) are defined only on Boolean arguments. They are negations of ^ and v; that is:

```

p^q ⇔ ~p~q
p~q ⇔ ~p^q

```

```
p←0 1
p←.∨ p

1 0
0 0

p←.∧ p

1 1
1 0
```

Non-Boolean Arguments

For non-Boolean numeric arguments, the expression $a∧w$ returns the least common multiple (LCM) of a and w , while $a∨w$ returns the greatest common divisor (GCD). For example:

```
12∨30
6
12∧30
60

12 30÷12∨30
2 5
∨/12 30÷12∨30
1

3.6∨4
0.4
3.6∧4
36

x←6250 8750 11250 16250
x←∨/x
5 7 9 13

y←0.03135 0.04389 0.05643 0.08151
y←∨/y
5 7 9 13

Fraction←17÷64
(Fraction,1)←∨/Fraction,1
17 64
```

Except when one of the arguments is 0, the GCD and LCM are related by a duality akin to DeMorgan's law for Boolean \wedge and \vee :

$$a\vee w \iff a \wedge^* w$$

When one argument is 0, the result of LCM is 0 and the result of GCD is the other argument.

Tolerant GCD and LCM

For arguments other than Booleans, *gcd* and *lcm* are subject to the visible value of *Oct*, comparison tolerance. Tolerant computation permits reasonable results with fractions that cannot be precisely represented. For example, the least common multiple of 0.6 and 1.4 is 4.2. This result is returned correctly with the default value of *Oct*. But if *Oct* is set to 0, APL fails to detect that each is an integer multiple of 0.2, and hence returns an LCM as if they had no common factor:

```
Oct
1.419697693e-14
.6 A 1.4
4.2
Oct=0
.6 A 1.4
3.02641895e15
```

┌ ┐

Right, Left; Dex, Lev

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
┌	Right	Right; Dex	[none]	00 00 00
┐	Left	Left; Lev	[none]	00 00 00

Dyads ┌ and ┐

The dyads *┌* and *┐* return one argument and ignore the other. The argument returned is the one to which the horizontal part of the symbol points:

```
a┌w ⇔ w
a┐w ⇔ a
```

The same principle applies to the monads. However, in that case there is no left argument. The definition becomes:

```
┌w ⇔ w
┐w ⇔ [No result]
```

Dex is used primarily to pass an argument cell into a composition without changing it. For example, the *cut* conjunction modifies a monadic verb to apply to each segment of an array argument. If you wish merely to select the segments without transforming them, *+* does it.

Left, or *lev*, is used primarily to assign a value that cannot otherwise be syntactically fitted into an expression. For example, mathematicians are fond of sentences in the form "x is such-and-such a function of y, where y is ..." That is really two sentences, linked by "where." In "A Dictionary of APL," Iverson illustrates a similar construction thus: *The following expression determines the coefficients c of a polynomial equivalent to a polynomial with roots r:*

```
c←s+.xp←rx.*t←s+(11+n)*.÷+t←t←bT1x/b←b←nP2←n+Pr
```

In this style, you start with the conclusion *c←s+.xp* and then fill in the subordinate definitions. If this were broken into a succession of short sentences, they would appear like this:

```
n←Pr
b←nP2
t←bT1x/b
s←(11+n)*.÷+t
p←rx.*t
c←s+.xp
```

In the foregoing, each of the segments linked by *←* assigns a value to a noun used in the root phrase. If there were no assignment, whatever is to the right of *←* would be completely discarded during evaluation. This might be the desired outcome when the material to the right is a comment, intended for the human reader but to play no part in the interpreter's execution. For example, in the following, the text that appears as the left argument of *+* is discarded, while the value to the right is passed through:

```
a←ax 'count to n'←n←'length of r'←Pr.
```

The verbs *←* and *+* are regular in their syntax and provide an alternative to the irregular separators *∘* and *⋈*.

T 1

Encode; Decode

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
T	[Undefined]	Encode; Represent	[none]	* 00 00
1	[Undefined]	Decode; Base	[none]	* 00 00

Dyad T

The dyad τ constructs the *representation* of each number in ω in the number system whose *base* (also called *radix*) is α . The dyad 1 is the inverse of encode, the *base value* of the representation ω in that number system.

For example, to represent a time interval recorded as 3723 seconds as a triplet in base $\alpha=24$ 60 60 (hours, minutes, seconds):

```
24 60 60 T 3723
1 2 3
```

And conversely:

```
24 60 60 1 2 3
3723
```

Relation Between Representation and Residue

A representation is calculated as a series of residues. This is made explicit in the following definition, which calculates a representation of ω in base α , when ω is an item and α is a list:

```

V z←α rep ω; pv; 1
[1] i←⊥10÷pv←α,α
[2] pv←weights α
[3] 101←(⊥10>1÷1-1)+0
[4] z[i]←α[i] | ω+pv[i]
[5] ω←ω-z[i]×pv[i]
[6] →10
■

```

In the definition, pv is the *position value* for the base. For example, in the familiar decimal system of representation, the right-most position is the units position, the next tens, the next hundreds, and so on. A length-4 representation in base 10 has position values 1000 100 10 1. The value of pv is calculated by the verb *weights*, defined thus:

weights: $1+\phi\kappa\backslash\phi\alpha,1$

No matter what the value of α , the value of the right-most position returned by *weights* is always 1.

Note that τ is *not* tolerant (that is, is not sensitive to $\square\text{ct}$).

There is a limit to the range of values that can be represented in a base of a given length. The largest integer representable in base α is $\alpha \uparrow \alpha - 1$. More generally:¹⁵

$$\alpha \uparrow \text{INT} \omega \leftrightarrow (x/\alpha) \downarrow \omega$$

rather than ω ; for example:

```
(3P10)T3247
2 4 7
10↓(3P10)T3247
247
```

The result 247 is $(x/3P10) \downarrow 3247$.

However, as a consequence of the definition of 0-residue, when the base begins with 0, there is no limit to the value of the first element of the representation and any necessary extra can be accumulated there:

```
0 10 10T3247
32 4 7
```

Since the last position in any representation is the *units* position, the fractional part of ω always appears in the last position of the result:¹⁶

```
(3P10)T247.33
2 4 7.33
```

Combining the previous two remarks, the 0 1 representation of a number separates its integer and fractional parts:

```
0 1T247.33
247 0.33
```

When a negative number is represented with a positive base, because the representation is derived from the x/α residue, the value returned is the *complement* in that base. For example:

```
(4P10)T-1
9 9 9 9      Tens complement of -1
```

¹⁵ With $\square\text{ct} \leftarrow 0$ so that \downarrow is not tolerant.

¹⁶ Fractional values may also occur in other parts of the representation when the base itself contains fractions.

```

      (4P16)T~1
15 15 15 15      Familiar (to those who use base-16) as FFFF

      0 1T~247.33
~248 0.67

```

Higher-Rank Arguments to T

Fundamentally, *encode* takes a number from ω and represents it according to a base specified in α . The number being encoded is an item. The base is specified by a list.

When ω contains many numbers, the result contains a representation for each of them. In the result, the representations are spread along the *first* axis;¹⁷ for example:

```

      (4P10) T 1987 2001 ~44
1 2 9
9 0 9
8 0 5
7 1 6

```

When α contains many bases, the result contains a representation for *each* number in *each* base.

Within α , the list that defines each base is spread along the *first* axis of α . For example, suppose you want numbers to be represented with base 10 10 10 10 and also with base 0 1000 1000 1000. The two bases must form a 4-by-2 array thus:

```

10      0
10 1000
10 1000
10 1000

```

Similarly, when α has shape 3 4 5, dyad T treats it as a 4-by-5 table of three-element bases.

In the result produced by T , each representation is spread along the *first* axis. When there are several representations for each number in ω , you get first the axes corresponding to the various representations, then the axes of ω . Thus:

$$\rho\alpha T\omega \iff (\rho\alpha), \rho\omega$$

¹⁷ This use of the first axis is inconsistent with the general rule that an argument cell occupies the *last* axis. The present convention was adopted in 1967 for the sake of parallelism between \downarrow and \uparrow .^{*} Representations along the last axis are achieved by conjoning represent with rank: $\alpha T^{\circ} \downarrow 0 \omega$; see "Forcing Representation Cells to the Last Axis", below.

For example, suppose *a* contains the two bases:

```
a←(4P10), ⍋0 1000 1000 1000
```

Then, the two representations of a single item are returned as a 4-by-2 table:

```
      a⍋1987
1      0
9      0
8      1
7      987
```

And the two representations of three items are returned as a 4-by-2-by-3 array, thus:

```
      a ⍋ 1987 2001 ~44
1  2  9
0  0  ~1

9  0  9
0  0  999

8  0  5
1  2  999

7  1  6
987 1  956
```

Forcing Representation Cells to the Last Axis

You can obtain a more consistent placement of the new axis (that is, putting it at the end) by using the rank conjunction *⍋* to specify explicitly the cells of each argument. When you do that, the standard rules for frame-building apply. For example, the following expression generates all the distinct representations possible in three binary digits and makes each representation a row of the resulting table:

```
      2 2 2⍋1 0 (12*3)-⍋10
0 0 0
0 0 1
0 1 0
0 1 1
1 0 0
1 0 1
1 1 0
1 1 1
```

By electing to modify τ with the rank conjunction, you give up its special rules for higher-rank arrays and instead apply the general rules for agreement of frames: either the frames must match, or, when one frame is empty, its single cell is paired with every cell in the other frame.

Dyad \perp

Dyad \perp is inverse to dyad τ . While τ generates the representation of a number in a particular base, \perp returns the numeric value of a representation ω , interpreted in base α .

As with τ , the base is described by a list. However, the base may also be an item, in which case APL treats it as a list having the same length as the first axis of ω .

As with τ , for each base there is a corresponding set of *position values*; they can be calculated by the same verb *weights* described in the preceding section, "Relation Between Representation and Residue". The base is 10 10 10 10, the position values are 1000 100 10 1.

The base-value of a representation is the sum of the numbers in the representation, weighted by their position values:

$$\alpha \perp \omega \iff +/\omega \text{weights } \alpha$$

For example:

```

       $\alpha \leftarrow 24 \ 60 \ 60$ 
       $\omega \leftarrow 1 \ 2 \ 3$ 
      
      3723

      weights  $\alpha$ 
      3600 60 1

      +/ $\omega$ weights  $\alpha$ 
      3723
```

Item Left Argument

When α is an item, it is treated as $(\neg 1 + \rho \omega) \rho \alpha$. Thus:

```

      2  $\perp$  1 0 1
      11
```

This permissive treatment of the left argument is possible for \perp but not for τ .

Higher-Rank Right Argument

Fundamentally, *base* takes a number-representation from ω and evaluates it according to a base specified in α . The representation being evaluated is a list, and the base is a list of the same length.

When ω contains many representations, the representations are assumed to be spread along the *first* axis. For example, suppose b is the following 4-by-3 table:

	b		
1	2	9	
9	0	9	
8	0	5	
7	1	6	

The base-10 values of its three representations are:

```
(4P10) ⍠ b
1987 2001 9956
```

When you provide a right argument of higher rank, the representations are still assumed to be spread along the first axis. For example, if ω is 4-by-5-by-6 array, APL treats it as a 5-by-6 array of four-item representations.

Higher-Rank Left Argument

The base is assumed to be spread along the *last* axis of α . For example, if you provide a 2-by-3-by-4 left argument, APL treats that as a 2-by-3 array containing six bases, each of four elements.

The result contains a base-value in each base, for each representation.

The shape-agreement rules for \cdot are the same as those for inner product. The last axis of α must match the first axis of ω . This axis disappears from the result (since the value is the weighted sum along it).

The remaining axes are reproduced in the result. The shape of the result is:

$$P \text{ @ } \alpha \cdot \omega \iff (-1 + P\alpha), (1 + P\omega)$$

Length-1 Base

As noted, when the left argument of \cdot is an item, it is treated as a list whose length matches the length of the representations in ω . More generally, whenever the last axis of α has length 1, it is assumed to apply to the representation in ω , and so is extended to match the length of the first axis of α .

Forcing Representation Cells to the Last Axis

Just as you can use the rank conjunction to force the representation to lie along the last axis of the result of τ , so you can force \perp to accept arguments in which the base is specified by the *last* axis of α , and representation cells are found along the *last* axis of ω .

Suppose b is a table containing two bases, 24 60 60 and 3600, thus:

```
      b
24 60 60
100 100 100
```

Then you can evaluate the representation 1 2 3 in each base by:

```
      b ⍳1 ⍒1 2 3
3723 10203
```

Or suppose c is the following four-column table:

```
      c
1 0 0 0
0 1 0 0
0 0 1 0
```

You can treat c as three representations, each of length 4, and evaluate each of them in base 0 24 60 60, thus:

```
      0 24 60 60 ⍳1 c
86400 3600 60
```

(This gives you the number of seconds in a day, an hour, and a minute.)

By electing to modify \perp with the rank conjunction, you give up its special rules for higher-rank arrays and instead apply the general rules for agreement of frames: either the frames must match, or the single cell in an empty frame is paired with every cell in the other frame.

Limitations on Inverse

In principle, τ and \perp are inverse to each other. But this is restricted in two ways:

- *Base.* The representation returned by $\alpha\tau\omega$ is in fact the representation of $(x/\alpha)\omega$. When ω is outside the range 0 through $^{-1}1+x/\alpha$, information is lost, and $\alpha\tau\alpha\omega$ is not equal to ω .
- *Higher-rank arguments.* When α is a table of bases, τ and \perp have different assumptions about how they are arranged and how they affect the result. The inverse relationship between τ and \perp holds only when

α is a list, or when both τ and \downarrow are modified by the rank conjunction, as $\tau\downarrow 0$ and $\downarrow\downarrow 1$.

Evaluation of Polynomials

If c is a table containing the coefficients of the successive terms of a polynomial, then $x\downarrow c$ evaluates the polynomial. The table of coefficients must contain a position for each term of the polynomial, in descending order; that is, starting with the coefficient for the x^n term and down, in order, to the constant (that is, the coefficient of x^0). This is the common order for the representation of numbers; however, polynomials are often written in the reverse order, with the low-order term first.

¶

Format

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
\uparrow	Format	Format	[none]	$\infty * *$

The *format* primitive \uparrow accepts any array as argument and produces a character representation of that array as a result.¹⁴

The result of \uparrow has the same rank as the argument, except in cases of formatting boxed arrays or non-character scalars. However, while axes other than the last have the same length as the argument, the last axis is often longer. Each numeric item in the argument is represented in the result by a format that usually requires several characters, perhaps including blanks as delimiters.

The representation of numbers is affected by the following system nouns:

Opp *Print precision.* The number of significant digits used by *monad* \uparrow .

Ops *Position and spacing.* Alignment within and between cells for display of an array of boxes by *monad* \uparrow .

Ofc *Format control.* Format conventions for *dyad* \uparrow .

Default Display

APL automatically displays the final result of any sentence that has a final result but does not assign that result to a name. Similarly, any noun assigned

¹⁴ The system verb $\uparrow\uparrow\uparrow$ provides a wider variety of formats than those available with \uparrow , controlled in a somewhat different fashion. It is described in Chapter 11, "System Nouns and Verbs".

to \square or \square is displayed. In these cases, where format need not (and cannot) be explicitly specified, the format is the same as that produced by monad \square .

Monad ∇

Monadic *format* converts an array whose items are numbers or boxes to a character representation. Packages are outside its domain. Applied to an array of characters, ∇w returns w unchanged; that is, $w\nabla w$.

Applied to an array of boxes, ∇w opens and formats the contents of each box independently, and then arranges the separate item-formats into a grid representing the structure of the array (as is explained later in this section).

Applied to a numeric array, ∇w returns a character array in which the numeric values are represented in one of three possible formats:

- *Fixed-point*. This form shows a leading zero only in the units position and does not print trailing zeros to the right of the decimal point. The decimal point appears only when there is a digit to the right of it (so *integer format* is simply a special case of fixed-point format). A negative number has a macron (high minus sign) before the first digit. For example:

```

      ▽7 8 12 + ¯8 8 ¯8
0.875 1 ¯1.5

```

- *Exponential*. This form, also called *scientific notation* or *engineering format*, consists of two parts, *mantissa* and *exponent*, joined by the letter *e*. In scientific notation, the mantissa is a number less than 10 and at least 1 (except when the number being represented is 0), written in fixed-point format. The exponent is an integer indicating the power of ten by which the mantissa must be multiplied. For example:

```

      ▽125 × 10*12
1.25e14
      ▽7 * 12 13
1.38412872e10 ¯9.688901041e10

```

Engineering format is similar to scientific notation, except that the exponent is always a multiple of three.

- *Complex*. This form consists of the real and imaginary parts linked by the letter *j*. The parts may be represented in any of the formats (integer, fixed-point, or exponential), independently of each other. For example:

```

      ▽27 + 0j1e12
27j1e12

```

When the imaginary part is 0, monad ∇ includes neither the character 0 nor the letter j (and the format of the real part is the same as fixed-point or exponential format). For example:

```

 $\nabla$ 50.36j47.52 + 3j4 4j5 * 0.12j-16
14 30.12j-15.88

```

Array-wide Format vs. Item-by-Item Format

Under some circumstances, a single format is adopted for an array as a whole, and all items are formatted and aligned in the same way. Under other circumstances, each item in an array is formatted independently.

An array-wide common format is adopted when:

- the array's rank is greater than 1
- no item in the array uses j format (that is, has a non-zero complex part).

Conversely, independent item-by-item formatting is adopted when:

- the array has rank 1 or less
- or
- any item in the array uses j format (that is, has a non-zero complex part).

When a common format is adopted for an entire array, either all items are shown in fixed-point format, or all items are shown in exponential format. In either event, all columns have a common *field width*.¹⁹ Within each field, the units position of each representation is at the same place, so that it is vertically aligned with the others.²⁰ In exponential format, the units positions of the mantissa are aligned.

Choice of Fixed-Point or Exponential Format for Real Numbers

When w is real²¹ APL selects a format as follows:

- A number²² whose magnitude lies in the range 10×10^{-6} to 10×10^{pp} is represented in *fixed-point* format.
- A number that is exactly equal to zero is represented as 0.
- A number outside those ranges is represented in *exponential* format.

¹⁹ See the discussion of "Field Width in Tables", later in this section.

²⁰ When there are decimal points, they are aligned too. But since the point is omitted when there are no digits after it, it is safer to say that the units positions are aligned.

²¹ "Real" is used here in the mathematical sense of "having no imaginary part"; it does not exclude integers.

²² Or part (real or imaginary) of a complex number.

Notice two useful consequences of these rules:

- In fixed-point format, no value of Ω_{pp} can discard digits to the left of the decimal point.
- A number for which APL's rules require exponential format could not be written more briefly in fixed-point format.

In an array having two or more axes and in which no element requires a j in its representation, APL uses *exponential* format for the entire array when any of the following is true:

- The largest magnitude in the array is greater than $10 \ast \Omega_{pp}$.
- The smallest magnitude in the array is less than $10 \ast -\Omega_{pp} + 4$.
- The range from the smallest to the largest magnitude exceeds a factor of $10 \ast \Omega_{pp} + 4$.

Mixed Formats in Representation of a List

In a list, APL selects fixed-point or exponential format for each of the items independently. For example:

```

       $\Omega_{pp} \leftarrow 5$ 
       $\nabla 0.2 \times 10 \ast 6 \times 10^{-3} + 16$ 
2e-13 0.0000002 0.2 2e5 2e11 2e17
```

Appearance of Fixed-Point Format

A number formatted by monad ∇ in fixed-point format is displayed with:

- no more than Ω_{pp} significant digits.
- no trailing zeros to the right of the decimal point.
- A leading zero to the left of the decimal point *only* in the units position.
- A decimal point only when there is a digit to the right of it.
- A macron (high minus) $\bar{}$ before the first digit of a negative number.

For example:

```

       $\Omega_{pp} \leftarrow 4$ 
       $\nabla \bar{\phantom{x}} - 10000 100 1 \div 3$ 
 $\bar{\phantom{x}}3333$ 
 $\bar{\phantom{x}}33.33$ 
 $\bar{\phantom{x}}0.3333$ 
```

Appearance of Exponential Format

In *exponential* format, each value being formatted is represented by a pair of numbers, the *mantissa* and the *exponent*, with an *e* between them.

The exact form of the mantissa depends on whether each item is formatted independently or there is an array-wide uniform format. When items are formatted independently, trailing zeros to the right of the decimal point are omitted, and the point is included only when there are digits to the right of it. For example:

```

      v10 11 12 * 10 -4 [pp+4]
1e10 2.594e10 6.192e10

```

However, with an array-wide uniform format, every item has the same mantissa format and the same exponent format. If any mantissa requires a decimal point, they all have one. If any requires positions to the right of the decimal point, they all do. The greatest number of trailing decimals is [pp-1].

The exponent is expressed as an integer. It may have one or two digits and perhaps a negative sign (when the magnitude being represented is less than 1). Space is allocated to accommodate the exponents needed for the actual data; at most, the exponent takes three print positions (to accommodate a negative two-digit exponent). For example:

```

      v3 2p10*2/5 6 7
1e5 1e5      There is only one digit before e
1e6 1e6      because all mantissas can be represented
1e7 1e7      by a single digit.

```

```

      v3 2p10*5 5 6 6 7 70
1e5 1e5      Both columns have space for a two-digit
1e6 1e6      exponent even though only one column
1e7 1e70     requires two digits.

```

```

      v-1 1 x3 1 +3 2p10*5 5 6 6 7 70
-1e5 1e5     Both columns have two positions before e
-1e6 1e6     even though only one column uses both
-1e7 1e70    of them.

```

```

      v(10*5 6 7), 3 1p10 11 12 * 10 -4 [pp+4]
1.000e5 1.000e10 The mantissas on the left have trailing
1.000e6 2.594e10 zeros to make them match the width
1.000e7 6.192e10 of mantissas on the right.

```

The exponent is always positioned flush-left next to the *e*. Thus, even when the letter *e* is aligned, the units position of the exponents is *not* necessarily aligned. For example:

```

      ⍶pp←4
      ⍷0 2, (+3)×10×10 11 -12
0.000e0
2.000e0
3.333e9
3.333e10
3.333e-13

```

Appearance of Complex Format

When any item in an array has a non-zero imaginary part, that item is displayed in complex format, with a *j* between the real and imaginary parts. (Conversely, in a complex array, an item whose complex part is zero is displayed in the usual fixed-point or integer form.)

The real and imaginary parts of each number are formatted independently; each may be in fixed-point format or in exponential format, without regard to the format of the other. There is no array-wide uniform format for an array in which any item is represented in complex format.

In a list, the representations of complex numbers may vary in length. Successive items are separated by one blank, thus:

```

      ⍷(- 2 4 6 8) ++3 -⍶pp←4
0.63j1.091 0.7937j1.375 0.9086j1.574 1j1.732

```

For an array of rank 2 or higher, each number's representation appears flush-right. Within the field devoted to a column of *w*, there is no attempt to align the letter *j* or either of the units positions.

```

      ⍷(- 6 8 0 66 68)++3 -⍶pp←4
0.9086j1.574
  1j1.732
      0
  2.021j3.5
  2.041j3.535

```

Field Width in Tables

Field width is the number of character-positions allocated to receive the representation of a number. When APL formats a table, it calculates a single value of field width for the entire table. The field width and the

location of the units position within it are calculated as though all the numbers were in a single column.

The field width adopted throughout an array is the minimum width in which all the values can be represented. The field includes an extra column for the negative sign only when needed to represent a value whose representation extends all the way to the left side of the field.

The maximum field width of an array in either fixed-point or exponential format is $6+\lfloor \log p \rfloor$.²⁸ Thus the rule for selecting one format or the other can be restated thus: fixed-point format is used *unless* it would require a width greater than $6+\lfloor \log p \rfloor$.

The field width of a complex array of rank 2 or greater is the length of the longest representation. The greatest possible width is thus 1 (for the letter *j*) plus $2 \times 6 + \lfloor \log p \rfloor$.

Blanks Between Columns

In every array having two or more axes and two or more columns, one column of blanks is inserted between adjacent fields.

Examples of Monad ∇

The following examples are intended to illustrate the points just mentioned. In particular, you can see that the same format is used throughout the display of a real numeric table:

```

       $\nabla$ 2 4P+1 2 1 2
1    0.5 1    0.5
1    0.5 1    0.5

       $\nabla$ 2 4P+3 1 2 3
0.3333333333 1    0.5    0.3333333333
0.3333333333 1    0.5    0.3333333333

       $\nabla$ -1 1 0..x 2 4P+3 1 2 3+ $\lfloor \log p \rfloor$ +5
-0.333333 -1    -0.5    -0.333333
-0.333333 -1    -0.5    -0.333333

      0.33333 1    0.5    0.33333
      0.33333 1    0.5    0.33333

```

²⁸For the exponential format, that is $\lfloor \log p \rfloor$ digits, plus the decimal point, the letter *e*, possibly a sign for the value and another for its exponent, and possibly two digits for the magnitude of the exponent.

Separation Between Planes of Higher-Rank Arrays

As noted at the beginning of this section, in general the result of ∇ has the same rank as its argument. In displaying any array of rank greater than 2, APL inserts an extra blank line to separate successive rank-2 segments (tables), two extra blank lines to separate successive rank-3 segments, and so on. You can see such a blank line in the preceding example.

Neither the *newline* character at the end of each row, nor the *newline* characters required to produce these additional separations, are part of the result of ∇ , but appear as a consequence of the number of axes in the result.²⁴

Format of an Array of Boxes

When ω is an array of boxes, $\omega\omega$ is always a table. Each of the boxes is opened and formatted independently, without regard to the formatting of any of the other boxes. The display of each box looks the way it would if the object within were to be displayed alone. The display for each box is a table, regardless of the rank of the object being displayed. When the array enclosed in the box has rank greater than 2, the separations between sub-arrays appear as extra rows of blanks.

The process of opening boxes and displaying their contents is recursive. That is, a box may itself contain boxes, and when it does, each is formatted according to the same rules.

When a table has been computed for each box independently, they are assembled into a grid corresponding to the structure of the array. However, the tables that represent the various boxes may vary in size. Each column (that is, each position along the *last* axis) is allocated a common width sufficient to accommodate the widest table in that column. Similarly, each row (that is, each position along the *next-to-last* axis) is allocated a common height sufficient to accommodate the tallest table in that row. This preserves the alignment of the boxes, albeit by creating a grid whose rows and columns vary in width. The effect – rather like a plaid blanket – is illustrated in Figure 5–10.

²⁴ However, when monad ∇ is applied to an array of boxes, the resulting representation never has rank greater than 2 and in that situation higher-rank arrays are indeed depicted by inserting additional blank rows.

Figure 5-10: Preservation of grid structure in formatting an array of boxes.

In Figure 5-10, where the grid provides a box more space than it needs, each box appears at the top left corner of its space.

Effect of $\square ps$ on Position and Spacing of Boxes

Each box is allocated height and width sufficient to accommodate the tallest box in its row or the widest box in its column. Unless the boxes have displays of the same shape and size, some will have more space allocated than they need. How boxes are positioned within the space available to them is controlled by the first two elements of the system noun $\square ps$. Vertically, boxes may be at the top, center, or bottom of the available space; horizontally, they may be at the left, center, or right. This control applies to the array as a whole; there is no direct provision to position some boxes one way and some another. The default value of $\square ps$ is $\begin{smallmatrix} -1 & -1 & 0 & 1 \end{smallmatrix}$.

To separate adjacent boxes, you can set $\square ps[3\ 4]$ so that additional blanks are inserted between the rows and columns. Provided $\square ps[3]$ and $\square ps[4]$ have a magnitude no less than 2, you may also elect to have horizontal or vertical demarcation lines around each box.

Position: The First Two Elements of $\square ps$

$\square ps[1]$	-1	At the top of the rectangle
	0	Vertically centered in the rectangle
	1	At the bottom of the rectangle
$\square ps[2]$	-1	At the left of the rectangle
	0	Horizontally centered in the rectangle
	1	At the right of the rectangle

Spacing: The Last Two Elements of $\square ps$

$\square ps[3]$	Magnitude	Number of positions separating vertically adjacent items
	When negative	Draw lines at top and bottom edges of boxes if space permits
$\square ps[4]$	Magnitude	Number of positions separating horizontally adjacent items
	When negative	Draw lines at left and right edges of boxes if space permits

When $\square ps[3]$ or $\square ps[4]$ is negative, the character \top is used to mark the top of a box, the character \perp to mark the bottom, and the character $|$ to mark the sides. Where a box touches the edge of the space assigned to it, the border characters surrounding the box overwrite the first of the separating blanks on that edge. For that reason, border characters may be drawn around a box only when there is space for them: that is, when the magnitude of the controlling item in $\square ps$ is at least 2.

At the edge of the result of $\vee w$ there are no separating blanks. There, the border characters are placed in an additional row or column. Thus, when $\square ps[3]$ is $\top 2$ or less, the result has two extra rows, one at the top and one at the bottom. Similarly, when $\square ps[4]$ is $\top 2$ or less, the result has two extra columns, one at the left and one at the right edge.

The following example illustrates the effects of $\square ps$ on an array of boxes:

```
B←2 2P(3 5P'AB')÷1 2÷'CD'÷'EFGHIJ'
VB -Ops+~1 ~1 ~3 ~3 a Top left, draw boxes
```

```

```
ABABA
```

```
BABAB 1 2
```

```
ABABA
```

```
CD EFGHIJ
```

Dyad ▽

The result of $\alpha \nabla \omega$ is a character array in the same way as the result of monad ∇ . The left argument permits more specific control of format and field width. It describes a series of *fields*, each to contain the representation of a *column* of ω . The fields are described in three different ways, depending upon whether α is *empty*, *numeric*, or *character*.

Empty α The right argument is formatted according to the rules for monadic format, as if the expression were $\nabla \omega$ instead of $\alpha \nabla \omega$.

Numeric α Each field is described by a pair of integers. In general, α is a list with twice as many items as ω has columns. The first member of each pair sets the width of the corresponding field. The second member of each pair sets the number of fractional positions or the number of significant digits.

Character α "Format by example." α is a character list having the same length as the last axis of the result. Embedded within α are characters indicating by example the position and format of the various fields.

Dyad ∇ with Empty α

When α is an empty vector, $\alpha\nabla\omega$ formats ω according to the rules for monadic format, as if the expression were $\nabla\omega$. This is useful when creating reports containing mixed character and numeric data:

```
name←4 5P'MariaPhil ElenaKen '
pay←4 1P 34000 125000 193000 17000
id←7 123 456 789 666
t←1 3P'Employee name ';>'Userid ';>'Salary '
⎕t⎕(';>5 0;>6 0)'>name>id>pay ⎕⎕ps←0
```

Employee Name	Userid	Salary
Maria	123	34000
Phil	456	125000
Elena	789	193000
Ken	666	17000

Dyad ∇ with Numeric α

When ω is numeric, $\alpha\nabla\omega$ formats each of its columns according to the specifications encoded in α . As with monad ∇ , "column" here means a position along the last axis.

The left argument α requires two integers to specify the format of a column of ω . Each pair of integers in α controls the formatting of a column of ω . Alternatively, α may be a single pair, which applies to *all* the columns of ω , or a single integer, in which case it is treated as if it were the pair $\overline{2} \uparrow \alpha$. Otherwise, *length error* occurs.

Within each α -pair, the first integer controls the *width* of the resulting representation. The second integer controls the *type* of representation (fixed-point or exponential), and the *number of places* to the right of the decimal point (in a fixed-point representation) or the *number of significant digits* (in an exponential representation).

Both types of representation, fixed-point and exponential, are *right-justified* within their fields. In fixed-point representation, the number of places beyond the decimal point is fixed and filled with trailing zeros.

To provide blanks for visual separation of fields, assign a width greater than needed to represent the values in ω , so that the field has leading blanks.

Fixed-Point Representation

The first member of an α -pair specifies the *total width* of the field. However, when the first member of the field is 0, the field is made wide enough to

accommodate the widest representation in that column, plus one leading blank.

The second member of an α -pair specifies the *number of places to the right of the decimal point*. When the number of places is greater than 0, an *additional position* is required for the decimal point itself. Unused positions to the right of the decimal point are filled with trailing zeros.

To represent a negative value in ω , the negative sign $-$ is inserted to the left of the left-most digit. When calculating the width required for a field, you should allow space for the negative values actually present in the data. When the field lacks space to print the sign for a negative value of ω , there is a *field overflow*. What APL does then depends on the value of $\Omega fc[4]$. (See the discussion of Ωfc later in this section or in Chapter 11, "System Nouns and Verbs".)

To illustrate formatting rules, consider the table m created as follows:²⁸

```
m←((+3) × 10*15) *.× 1 1 1 -1 -1 pp=5
  ωm
3.3333      3.3333      -3.3333
33.333      33.333      -33.333
333.33      333.33      -333.33
3333.3      3333.3      -3333.3
33333      33333      -33333
```

To show the boundaries of the result, catenate brackets to the left and right:

```
'[',(8 2ωm),']'
[ 3.33 3.33 -3.33]
[ 33.33 33.33 -33.33]
[ 333.33 333.33 -333.33]
[ 3333.33 3333.33 -3333.33]
[33333.3333333.33*****]
```

At the lower left, representations run together because a field width of 8 is insufficient to leave an initial blank. At the lower right, there is field overflow because field width 8 is insufficient to represent the number -33333.33 .

Field width 0 causes ω to calculate the width of the fields. A single pair beginning with 0 computes the minimum common field width for the entire array:

²⁸ Recall that Ωpp affects monad ω but not dyad ω .

```

      '[(, (0 2 1, m), ')]'
[      1.00      3.33      3.33      ~3.33]
[      1.00      33.33     33.33     ~33.33]
[      1.00     333.33     333.33     ~333.33]
[      1.00    3333.33    3333.33    ~3333.33]
[      1.00   33333.33   33333.33   ~33333.33]

```

Specifying 0 2 for each field separately permits each column to be assigned its own width, independently of the others. It allows space for a negative sign whether or not there is one in the corresponding column of w .

```

      '[(, (0 2 0 2 0 2 0 2 w 1, m), ')]'
[      1.00      3.33      3.33      ~3.33]
[      1.00      33.33     33.33     ~33.33]
[      1.00     333.33     333.33     ~333.33]
[      1.00    3333.33    3333.33    ~3333.33]
[      1.00   33333.33   33333.33   ~33333.33]

```

Exponential Representation

When the second member of an α -pair is *negative*, the result is represented in *exponential form*. The first item of an α -pair sets the total width of the field, while the absolute value of the second member specifies the number of significant digits. In an exponential representation, positions are required as follows:

- The *last three* positions of each field are reserved for the exponent and its sign. They are set flush-left within those three positions; unused positions are filled with blanks.
- The *fourth* position from the end is reserved for the character *e*.
- In the remaining leftward positions, there must be space for the following:
 - The decimal point.
 - The number of digits specified in the first member of the pair. The first of these digits appears to the left of the decimal point; the others appear between the decimal point and the character *e*.
 - A negative sign, if required for the value being represented.

In general, the total width must be at least 6 greater than the number of significant digits requested. However, when the value being represented is not negative, a width 5 greater than the number of significant digits suffices.

Any unused positions at the left of the field are filled with blanks. The following illustrates some of the points mentioned:

```

t←2/7 (10+3) × 1 -1 1e-30
*[*, (8 -3 15 -3 ∇ t), ']'
[3.33e0      3.33e0  ]
[*****      -3.33e0  ]
[3.33e-30    3.33e-30]

```

Dyad ∇ with Character α

When α is a character array, the expression α∇ω is called *format by example*: α provides a *pattern* for the result. The right argument ω is a numeric array of any rank. The left argument α is a *list* of the same length as the last axis of the desired result and shows how each column of ω is to be represented.

The system noun ⌊fc is an implicit argument to dyad ∇ and controls how it treats certain cases, as explained below.

Numeric Fields within the Pattern

The left argument α consists of a series of numeric "fields," optionally embedded in non-numeric text. The representations of the numbers in ω replace the numeric fields of the pattern. α must contain either a numeric field for each column of ω or a single numeric field that is then applied to all columns of ω.

A numeric field must contain at least one digit. It may also contain the characters . (dot) and , (comma). Collectively, the digits 0 through 9 and the dot and comma are called *control characters*. (Whether a dot or comma serves as a control character depends on context, as explained below.)

A field is bounded by *blanks* or (on the right) by the first non-control character occurring further right than a 6. For example, the following has three numeric fields, pointed out by the arrows shown below. The first numeric field is ended by the colon, since colon is the first non-control character to the right of the 6.

```

'Part # 05555-60: Stock 55550 Updated 55/55/55'
      ++++++          +++++          ++++++

```

Although the presence of one or more blanks serves to delimit a field, each blank is reproduced in the result.

The digits in a field reserve places in the result to receive the representation of a number. If they fail to provide sufficient positions, there is a *field overflow*. In the result, the numeric field for that value is shown only by asterisks (or by the character you indicate in ⌊fc[4]).

By their values, the digits in the pattern's numeric fields indicate how the number is to be formatted. Much of what follows concerns the effect of the digits 0 through 9 on the representation of a number.

The examples that follow make use of a user-defined verb *on*. It shows the left argument of *▽* and then the result, aligned one above the other so that you can compare the result with the "picture" that controlled it. The argument of *▽* is shown with a row of dashes before and after it, thus:

```
a←'550 # $340.10CR ea. = $3,540.10CR'
d←3 2P10 188.4 2 ~4 20 .12
a on a ▽ d,x/d
-----
550 # $340.10CR ea. = $3,540.10CR
-----
10 # $188.40 ea. = $1,884.00
2 # $4.00CR ea. = $8.00CR
20 # $0.12 ea. = $2.40
```

Decorators within the Pattern

Characters that are not control characters are called *decorators*. In the preceding example, the characters #, \$, CR, ea., and = are decorators. So were the texts *Part #* and *Updated* in the earlier example, and the hyphen and slashes, even though they were embedded within a numeric field. In general, decorators are simply reproduced unchanged in the result. Those that are always reproduced and never float are called *simple decorators*.

A *controlled decorator* is text attached to the beginning or end of a numeric field, usually to indicate the *sign* of the number there represented. In the example, \$ and CR are controlled decorators because each of them abuts a numeric field.

A controlled decorator *floats*: that is, it moves inward to occupy positions that the pattern reserved for the number's representation, but that were unneeded for the value being represented. In the pattern, a controlled decorator is a sequence of one or more characters that:

- does not contain a blank
- is located immediately to the left of the numeric field's first digit, or immediately to the right of its last digit.

The way the controlled decorator text appears in the result is controlled by the presence of the digits 1, 2, or 3 in the numeric part of the pattern. (If the pattern does not contain one of those three digits, or there is a 4 somewhere between the decorator text and the number 1, 2, or 3, text that would otherwise be a controlled decorator is treated as a simple decorator.

Treatment of the Decimal Point and Decimal Digits

In the result, the digits of a number's representation replace positions in the pattern's numeric field that contain digits. A decimal point can appear in the result *only* when it occurs as part of the pattern's numeric field. Moreover, the fractional part of a number can be represented in the result *only* when the pattern contains both a decimal point and one or more digits to the right of it.

When the pattern provides fewer positions for decimal digits than the representation requires, the representation is rounded at the right-most position provided. Thus, if you provide two decimal positions, a representation that requires more is rounded to the nearest hundredth. Similarly, if you use a pattern that makes no provision at all for decimals, the result is rounded to the nearest integer:

```
a='555,550 no decimals vs. 550.555'
a on a ⍷ 2/γ+15
```

```
-----
555,550 no decimals vs. 550.555
```

```
-----
1 no decimals vs.      1
1 no decimals vs.      0.5
0 no decimals vs.      0.333
0 no decimals vs.      0.25
0 no decimals vs.      0.2
```

Treatment of the Sign

The sign is represented in the result by the *controlled decorator* in the pattern. Controlled decorator text can appear in the result in three ways: only for negative values, only for non-negative values, or for any values, regardless of sign. Controlled decorator text floats.

The following are the digits that affect controlled decorator text. (For details and examples, see the description of the various following control digits, later in this section.)

- 1 Include and float the controlled decorator text for a *negative* value.
- 2 Include and float the controlled decorator text for a *non-negative* value.
- 3 Include and float the controlled decorator text regardless of value.
- 4 Block the effect of 1, 2, or 3 when interposed between them and a decorator text.

The following illustrates a decorator to mark negative values:

```
a←'On 05/05/05, balance was (55,510.50)'
w on a v 880611, r1 '1 1 1 1 *2/23456.71 456.7
```

```
-----
On 05/05/05, balance was (55,510.50)
-----
```

```
On 88/06/11, balance was 23,456.71
On 88/06/11, balance was (23,456.71)
On 88/06/11, balance was 456.70
On 88/06/11, balance was (456.70)
```

A negative number can be represented in the result *only* when the pattern includes a controlled decorator text *and* the numeric field includes a 1 (meaning "Include the controlled decorator when the value is negative").²⁶

When your pattern fails to provide for a negative value but *w* contains one, you have an *overflow* condition. The numeric field for that number is replaced by asterisks.²⁷

A negative value is marked in the result by whatever text you provide. There may be controlled decorator text on *both* sides of the numeric field, or only before or after. Note that if you want a leading macron as negative sign, you still have to say so explicitly; format by example does *not* have a default negative sign.

Alternative Conventions Regarding Decimal Point and Grouping

In the left argument of *v*, only a dot can indicate where the decimal point is to be located; only a comma can indicate a grouping symbol to be inserted between digits. However, different characters may appear in the result, in accordance with national convention. In the result, the character that separates integer from fraction is `⎕fc[1]`; it replaces the dot that indicates the decimal point in the pattern. In the result, the character that separates groups of digits is `⎕fc[2]`; it replaces the commas that indicate grouping in the pattern. For example:

²⁶ Well, not quite only. You can represent the magnitude of a negative value when the numeric field includes a 3, but since the controlled text is then included regardless of sign, you have lost the distinction between negative and non-negative values.

²⁷ Alternatively, depending on how you set `⎕fc[4]`, you may substitute some other character to indicate overflow or to report a domain error. See the discussion of `⎕fc` later in this section or in Chapter 11, "System Nouns and Verbs".

```

Dfc[1 2]←1, '
a←'555,555,555,550.555,555,555'
a on a?1.5+2×16
-----
555,555,555,550.555,555,555
-----
          3,323 350 97
        52,342 777 785
       1 871,254 305 798
      119 292,461 994 609
     11 899 423,083 962 248
    1 710 542 068,319 573 16

```

In the pattern, a dot indicates the decimal point when:

- it precedes the first digit or it is surrounded by digits in a numeric field
- and*
- it is the only such dot in the field.

Thus, in the following pattern, the dot in 5.5 is the decimal point, but the sequence of three dots is simple decorator text (and reproduced in the result):

```

a←'5...55.55'
a on a? 4 1P 1 12.3 123.45
-----
5...55.55
-----
... 1
...12.3
1...23.45
... 1

```

Dot and Comma

The dot and comma are *conventional decorators*; they specify decimal digits or group separators according to common conventions (as in 23,456.78).

A comma is a *grouping decorator* when it is surrounded by digits in a numeric field. Thus, in the following pattern, the sequence 5,5 indicates where a grouping comma should be inserted. The other commas are not grouping commas because they are not surrounded by digits on both sides. In the result, a grouping comma appears wherever the result has a digit on both sides of it. Other commas appear according to the usual rules for

decorator text. Thus the comma in *Left*, is not a grouping comma and neither are the double commas.

The phrase *Left*, and the right-most comma in the pattern are sign decorators; because of the number 2 in the picture, they are included (and float) for non-negative values. The word *Right* is not part of the sign decorator (since there is a space between it and the rest of the picture). Thus the double comma and the word *Right* appear in every field of the result.

```
a←'Left,55,,525,5, Right'
a on a ⍷ ⍶12345 ~12345 3 ~3 123 ~123

-----
Left,55,,525,5, Right
-----
Left,1,,234,5, Right
1,,234,5, Right
Left,,, 3, Right
,, 3 Right
Left,,, 12,3, Right
,, 12,3 Right
```

A decimal point not followed by a numerical digit is a part of the trailing decorator and as such is included or excluded in the same way as any other part of the controlled decorator text. For example:

```
a←'-5125.POS'
a on a ⍷⍶123 ~123

-----
-5125.POS
-----
123.POS
-123
```

Significance of the Control Digits 0 to 9

The control characters 0 to 9 are described here in numerical order.

- 0 *Leading/trailing zeros.* Unused positions are filled with 0 from here towards the decimal point. For example:

```

a←'55,550.0055'
a on a ¯ 1 0 1000.1, +3
-----
55,550.0055
-----
1.00
0.00
1,234.50
0.3333

```

If you do not specify any position at which a leading or trailing zero is printed, a zero value has no printed digits. The decimal point also turns into a blank when there is no digit to the right of it.

```

a←'[555.55]'
a on a ¯ 4 1 0 10.1 100
-----
[555.55]
-----
[ 1 ]
[ ]
[ 10.1 ]
[100 ]

```

- 1 **Negative values.** The controlled decorator texts next to the number's representation are included and float inward until they touch the number's outermost printing digits. However, when the value being represented is not negative, the controlled decorator is replaced by blanks. For example:

```

a←' Value (1550.50)'
a on a ¯ 1.23 ~12.34 123.4 ~123.4
-----
Value (1550.50)
-----
Value      1.23
Value    (12.34)
Value   123.40
Value  (123.40)

```

- 2 **Non-negative values.** The controlled decorator texts next to the number's representation are included and float inward until they touch the number's outermost printing digits. However, when the number being represented is negative, the controlled decorator is replaced by blanks. For example:

```
a←' Value +2550.50Plus'
a on a ⍷1.23 12.34 123.4 123.4
```

```
-----
Value +2550.50Plus
-----
Value      +1.23Plus
Value      12.34
Value     +123.40Plus
Value      123.40
```

- 3 *Float.* For all values, the controlled decorator texts next to the number's representation are included and float inward until they touch the number's outermost printing digits. (Notice that in the following example the result does not distinguish the sign of the argument.)

```
a←'%%[35,550.55]%%'
a on a ⍷ 81.23 2 3333 .4
```

```
-----
%%[35,550.55]%%
-----
%%[81.23]%%
%%[2]%%
%%[3,333]%%
%%[0.4]%%
```

Two of the control characters 1, 2, and 3 may occur in the same pattern. (It is not illegal to put more than two, but since there are only two controlled decorator texts, left and right, only the outer two control characters are effective.) When there is more than a single occurrence of 1, 2, or 3, inclusion of each decorator text is governed by the control character encountered first, scanning from the decorator towards the numeric part of the pattern. For example, the pattern

```
' +215550.50Overdraft'
```

causes + to be printed to the left of a non-negative value because, scanning from the left, 2 is the first relevant control character encountered. Similarly, *Overdraft* appears to the right of a negative value because, scanning from the right, 1 is the first relevant control character.

The effects of the digits 1, 2, and 3 do not depend on where they are located with respect to the decimal point.

- 4 *No float.* The action of a 1, 2, or 3 is nullified by a 4 that occurs between the 1, 2, or 3 and the decorator text. If the preceding example is modified by introducing a 4 somewhere to the right of the 3, the right decorator text is now reproduced in place for all values, but the left decorator text continues to float inward, as before:

```
a~'%%[35,550.55]%% %%[35,450.55]%%'
a on a ~ 2/81.23 2 3333 .4
```

```
-----
%%[35,550.55]%% %%[35,540.54]%%
```

```
-----
%%[81.23]%%      %%[81.23]%%
%%[2]%%          %%[2  ]%%
%%[3,333]%%      %%[3,333  ]%%
%%[0.4]%%        %%[0.4  ]%%
```

- 5 *Normal digit.* The position is available for a digit. If the representation of a particular value does not require the leading or trailing positions, the controlled decorator text moves in to occupy them (but only when a decorator text has been supplied and is controlled by the presence of a 1, 2, or 3 in the pattern).
- 6 *Field delimiter.* The next rightward non-control character (that is, any character other than 0123456789..) starts a new field. This is needed where fields are not separated by blanks. The digit 6 provides an additional field break at the next non-control character. For example, this allows you to include slashes rather than blanks as field delimiters to format three integers (for example, to represent a date):

```
'0556/06/05' ~ 1988 11 4
1988/11/04
```

- 7 *Exponential format.* The value is represented in exponential notation. The next rightward non-control character (for example, a) separates the *mantissa* from the *exponent*. The decimal point (which must be somewhere to the left of the 7) marks the decimal point of the mantissa.

Your pattern must provide at least one digit to the left of the point. If a value to be formatted is negative, it needs another position for the sign. By convention, in *scientific format* the mantissa has exactly one digit to the left of the point and the exponent is adjusted accordingly. For example, 1988 is represented as 1.988e3. To achieve that, use 1 to mark the leading digit, with the character you are using as a negative sign to the left of it.

It is possible to specify more than one digit to the left of the point. APL selects the exponent to match the number of digits to the left of the point. For example, when you provide two digits to the left of the point, APL selects an exponent that is a multiple of 2. If your pattern has three digits to the left of the point, APL provides an exponent that is a multiple of 3. This is the convention known as *engineering format*. Compare the left field (scientific) with the right field (engineering) in the following:

```
a←'1.75E5 VS 155.75E5'
a on a ⍷ 2/10*0,18
```

```
-----
1.75E5 VS 155.75E5
-----
```

```
1.00E0 VS 1.00E0
1.00E1 VS 10.00E0
1.00E2 VS 100.00E0
1.00E3 VS 1.00E3
1.00E4 VS 10.00E3
1.00E5 VS 100.00E3
1.00E6 VS 1.00E6
1.00E7 VS 10.00E6
1.00E8 VS 100.00E6
```

- 8 **"Check protection."** Unused positions from here to the decimal point are filled with the character specified in `Qfc[3]` (which by default is *).

```
a←'$558,555,535.50'
a on a ⍷ 4 1P123 12345 1234567 123456789
```

```
-----
$558,555,535.50
-----
```

```
$*****123.00
$***12,345.00
$1,234,567.00
$123,456,789.00
```

- 9 **Conditional zero-fill.** Like positions marked by 0, these positions are filled with the character 0 when not otherwise used in the representation of a number. However, when the value being represented is zero, these positions are left blank. In this fashion, an item whose value is zero may be represented by a blank field in the result. (Compare the following with the example for control digit 1, earlier.)

```
a←'55,559.9955'
a on a ⍷ ⍶ 1 0 1234.1, +3
```

```
-----
55,559.9955
-----
```

```
1.00
```

```
1,234.50
0.3333
```

Effect of $\square fc$ on ∇ Format by Example

The system noun $\square fc$ is used as an implicit argument to ∇ , affecting the result of its dyadic use with a character left argument. It contains six elements, which are used as follows:

- $\square fc[1]$ *Decimal.* Character to separate the integer part from the fractional part of a number. Where the left argument α contains the character $.$ used as a decimal point, the result of $\alpha \nabla \omega$ substitutes $\square fc[1]$ for $.$. In a clear workspace, $\square fc[1]$ is $.$.
- $\square fc[2]$ *Grouping.* Character to separate groups of digits in the representation of a number. (The groupings are conventionally but not necessarily triplets.) Where the left argument α contains $,$ surrounded on both sides by digits, the result of $\alpha \nabla \omega$ substitutes $\square fc[2]$. In a clear workspace, $\square fc[2]$ is $,$.
- $\square fc[3]$ *Check protection or fill.* Character to mark insignificant positions in the representation of a number. Where the left argument α contains 8 and the corresponding digit in the result is not significant, the result substitutes $\square fc[3]$. In a clear workspace, $\square fc[3]$ is $*$.
- $\square fc[4]$ *Field overflow.* Character to indicate that the representation requires more space than has been specified in the left argument α . In the result, the entire field is replaced by $\square fc[4]$. However, when $\square fc[4]$ is 0 and any of the numbers in ω cannot be represented in the space provided, the entire expression is rejected with a domain error. In a clear workspace, $\square fc[4]$ is $*$.
- $\square fc[5]$ *Blank.* Character to indicate where a blank should be substituted in the result. This is useful when you would like the result to have a blank within a numeric field or within a controlled decorator. Where the left argument α contains this character as a *controlled character* (that is, embedded within the positions devoted to the number's representation), the result contains a blank where the pattern contains $\square fc[5]$. In a clear workspace, $\square fc[5]$ is $_$.
- $\square fc[6]$ *Negative Sign.* This position is reserved for a character to indicate a negative value. However, at present the only permitted value is $-$. That is the value of $\square fc[6]$ in a clear workspace.

⌘

Execute

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
⌘	Execute	[undefined]	[none]	* * *

Only the monad **⌘** is defined. APL treats the character list (or item) *w* as a *line to be executed*, in the same way as a line in the definition of a verb, or a line entered from the keyboard, is executed.

The argument *w* may contain only executable characters. In general, executable characters are those enterable from the keyboard. (See "APL Character Set" in Chapter 3, "Nouns and Pronouns")

The result of **⌘w** is the result of evaluating the sentence represented by the character list *w*; for example,

```
⌘'2+2'
```

```
4
```

```
⌘'A←3+4'
```

assigns the value 7 to the name A.

The verb **⌘** permits an APL program to construct statements to be executed. Some uses of **⌘** are:

- conditional execution
- conversion of numeric constants
- passing unevaluated arguments to user-defined verbs.

To illustrate *conditional execution*, consider processing a user's response to the question *Proceed to execute Work?* with a statement using **⌘**:

```
⌘('Yes'≡3+□)/'Work'
```

The verb **⌘** can *convert character lists* representing numeric constants to their numeric values; for example:

```
⌘⌘'1 2 3'
+⌘
```

```
⌘
```

In this rather limited sense, **⌘** is *inverse* to **⌈**. (See also the discussion of **⌈f1** and **⌈v1** in Chapter 11, "System Nouns and Verbs".)

Since system commands are *not* APL statements, they *cannot* be executed by **⌘**; it follows that the first non-blank character in the argument of **⌘**

may *not* be `⌵`. Nor may `⌵` be used to invoke the V-editor, and so the first non-blank character may *not* be `⌵`.

The verb `⌵` can occur in the sentence that is the argument of `⌵`, so that the verb is used recursively.

Result of `⌵`

Whether `⌵` has a result depends upon whether the sentence represented in its argument, when evaluated, has a result. When it does, the result of evaluating the sentence becomes the result of `⌵`. Otherwise, `⌵` has no explicit result. For example,

```
⌵'1+2×10.5×ρv'
```

returns a result. However, certain primitives have no result (for example, monad `⌵`, and system verbs such as `⌵pdef` or `⌵tie`). A user-defined verb may be written so that it does not return an explicit result. When the executed sentence has no explicit result, then the verb `⌵` has no result. For example:

```
⌵'⌵'1+2×10.5×ρv'
```

[no result]

A sentence that has a result can be embedded in a larger sentence; for example:

```
⌵⌵'1+2×10.5×ρv'
```

A sentence that lacks a result cannot be embedded in a larger sentence:

```
⌵⌵'⌵'1+2×10.5×ρv'
```

result error

```
⌵⌵'⌵'1+2×10.5×ρv'
```

■

The sentence `⌵'⌵'` has no result.

Display of Result

When the verb `⌵` returns a result, the result is displayed if the result would normally be displayed; that is, `⌵'⌵+15'` displays a value, but `⌵'⌵+15'` does not.

Evaluation of Multiple Sentences

The argument of `⌵` is treated in the same way as a *line* entered from the keyboard or within a user-defined verb. Thus, the argument may contain

several sentences delimited by the \circ character. It is also permissible to include a final comment to such a line, or an initial label. These are permitted on the principle that the domain of Δ should include anything that would be legitimate in the body of a user-defined verb. When the argument of Δ contains a label or comment, both the label and the comment are ignored.

Several sentences can be evaluated in a single use of Δ if they are included in the argument separated by diamonds; for example:

$$z \leftarrow \Delta \text{ 'a+b/10b } \diamond x+y/10y'$$

When the argument of Δ contains more than one sentence, the result returned by Δ is the value resulting from the *last* sentence evaluated. In the preceding example, $x+y/10y$ is the last sentence evaluated, and the value assigned to z becomes the value of $y/10y$ in the same way as it would if the sentence were $z \leftarrow x+y/10y$.

Occurrence in the State Indicator

If Δ has been invoked but has not completed execution, it appears in the state indicator on a line of its own, in the same way as a user-defined verb. For example, when fn is a verb invoked by $\Delta \text{ 'fn'}$ and its execution is suspended on line 3, then the state indicator appears as:

```

)SI
fn[3] Δ
Δ

```

In the state indicator, Δ is represented by a line containing simply the symbol Δ . In $\Omega 1c$ (the line counter), there is a corresponding item whose value is the line number of the line that invoked Δ . Similarly, in the table $2 \text{ } \Omega ws \text{ } 2$, there is a row corresponding to a current use of Δ . (See the discussions of $\Omega 1c$ and also Ωws in Chapter 8, "Control of Execution").

Branch within Execute

When a sentence evaluated by Δ contains a branch arrow, \rightarrow the effect is the same as if the statement had been encountered as part of the defined verb nearest the top of the state indicator.

$$\Delta \text{ ' } \rightarrow w' \iff \rightarrow \Delta w' \iff \rightarrow \Delta w' \iff \rightarrow w'$$

If the value to the right of \rightarrow is in the domain of \rightarrow , the branch is taken. (See Chapter 8, "Control of Execution", for further discussion of branching.)

Errors Encountered During Execution

When the sentence you try to execute contains an error, APL reports an error in the usual way. That includes generating an error message, a display of the offending sentence, and a caret to mark where in the statement it was working when it noticed the error. Execution is suspended on the sentence that contains *a*, not on the line which was the argument to *a*. However, the sentence displayed in the error message is the argument of *a*, not the sentence that invoked it.

For example, suppose a user-defined verb called *run* contains on line 4 the sentence *x←a command*. Suppose that, by the time APL gets to this statement, *command* is the name of the character list 'fix y'. But that is not an executable statement because *fix* has not been defined.

In this case, rather than telling you that the error is on line 4 of *run*, APL shows the statement it is trying to execute (rather than the one that invoked *a*), thus:

```
value error
run[4]a fix y
      ^
```

The *a* symbol is displayed in front of the sentence that *a* has been asked to execute. To clarify how the defective sentence was created, the display shows one *a* symbol for each level of invocation of *a*. For example, if the invoking sentence says

```
x←a command
```

and the value of *command* was set by

```
command←'a'⍪0''
```

the error message shows the execute symbol twice, like this:

```
domain error
run[4]aa 0
      ^
```

Signal within Execute

When `⌈signal ω` occurs within the argument of *a*, the effect is to abort execution of *a* and signal the event identified in *ω*. The signal is sent to the environment in which `⌈signal ω` occurred. Notice that the effect of `⌈signal ω` is not the same as the effect of `⌈signal ω`. They differ both in the activity aborted by `⌈signal` and the environment that receives the signal.

For example, when a user-defined verb *foo* contains the sentence (without *a*),

```
⊞signal ω
```

execution of *foo* is aborted, and event *ω* is signaled to the sentence that invoked *foo* (and that is therefore next below it on the state indicator).

But when *foo* contains the sentence

```
a'⊞signal ω'
```

only *a* is aborted. The event *ω* is signaled to the sentence that invoked *a* (that is, to the verb *foo*, which appears below *a* in the state indicator).

7 , Table, Ravel; Join

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
⍒	Table	On; Above	[none]	∞ ∞ ∞
,	Ravel	By; Beside	[none]	∞ ∞ ∞

The monad *,* *ravels* (that is, relaxes the structure) of an existing array. The monad *⍒* forms any array into a table. As dyads, the verbs *,* (*comma*) and *⍒* (*comma-bar*) produce a single array by joining their two argument arrays.

Monads *,* and *⍒*

The expression *,*ω ("ravel ω") returns a *list* containing all the items of ω in row major order. For example:

```
⍒
One
Two
Three
```

```
,⍒
One Two Three
```

The ravel of an item is a one-element list.

The expression *⍒*ω ("table ω") returns a *table* in which each row is the ravel of a major cell of ω. For example, suppose *X* is a 2-by-3-by-5 array, thus:

```

      x
abcde
fghij
klmno

```

```

pqrst
uvwxy
z0123

```

Then τx is a 2-by-15 array as follows:

```

       $\tau x$ 
abcdefghijklmnop
pqrstuvwxyz0123

```

Similarly, when ω is a 2-by-3-by-4-by-5 array, $\tau\omega$ is a 2-by-60 table.

The result of monad τ always has rank 2. When ω is a list, $\tau\omega$ is a one-column table. When ω is an item, $\tau\omega$ is a 1-by-1 table.

Formally, $\tau\omega$ is related to ω by the identity

$$\tau\omega \iff ,\omega^{-1} ,\omega^{-1} \omega$$

in which the second occurrence of ω^{-1} is needed only to cover the case when ω is an item.

Figure 5-11 illustrates the effect of τ with the rank conjunction applied in various ways to a rank-5 array. a is a 2-by-2-by-2-by-2-by-2 array. Successive sections of the figure show the result and the shape of the result for $\tau^{\circ}5$ and for $\tau^{\circ}4$, for $\tau^{\circ}3$, for $\tau^{\circ}2$, and for $\tau^{\circ}1$. The result of $\tau^{\circ}0$ a is not shown. It has shape 2 2 2 2 2 1 1, and does not fit conveniently on a page, even in small type.

a←1 2 2 2 2 2 2 abcdefghijklmnopqrstuvwxyz.....'					
	SHAPE	RESULT		SHAPE	RESULT
v5 a	2 16	abcdefghijklmnop qrstuvwxyz.....	v1 a	2 2 2 2 1	a b c d e f g h i j k l m n o p
v4 a	2 8	abcdefgh ijklmnop qrstuvwx yz.....			
v3 a	2 2 4	abcd efgh ijkl mnop qrst uvwx yz..			
v2 a	2 2 2 2	ab cd ef gh ij kl mn op qr st uv wx yz			

Figure 5-11 : Effect of monad τ at ranks 5 through 1

Dyads $\alpha\tau\omega$ and τ

The dyad $\alpha\tau\omega$ joins α and ω along their *major* (that is, first) axis. The dyad α, ω also joins two arrays, but along the *last* axis. Applied to tables, $\alpha\tau\omega$ joins them vertically, while α, ω joins them horizontally.

In general, the arrays thus joined must have the same rank. However, their ranks may differ by 1, or one of them may have rank 0.

Dyad τ is related to dyad τ by the identities:

$$\alpha, \omega \iff \alpha\tau'\omega \iff \tau(\tau\alpha)\tau(\tau\omega)$$

Restrictions on the Domains of τ or τ

The arrays being joined must be of the same type (character, number, or box).

When both arguments are numeric but use different internal representations for numbers (Boolean, integer, floating, or complex), the result has the internal representation of whichever argument has the more extensive representation.

When one of the arrays being joined is empty, the result has the type of the non-empty argument. When both arguments are empty, the result has the type of the right argument.²⁸

Shape of Arguments and Result

The arrays being joined must have the same length in all their axes *except* the axis along which they are to be joined. Arrays joined by $\alpha\tau\omega$ must have the same length in all axes *except* the *first*, and arrays joined by α, ω must have the same length in all axes *except* the *last*.

If the arrays are not of the same rank, then either one of them must be a scalar, or of rank which differs from the other by one. If they differ by one in rank, the array of lesser rank is treated as if it had length 1 along the axis of joining. If one is a scalar, it is treated as an array of the same shape as the other except along the axis of join, which is treated as length 1. For example:

```
⍣ a+2 3P'abcdef'
```

```
abc
def
```

²⁸In principle, the type of an empty array is immaterial. However, the type becomes evident when an empty array is expanded with τ or τ . An empty array may be character or numeric. (An empty array discarded from an array of boxes is numeric.)

```

      a, 'XY'
abcX
defY
      a,2 1P'XY'
abcX
defY
      aT'XYZ'
abc
def
XYZ
      aT1 3P'XYZ'
abc
def
XYZ
      a, '+'
abc+
def+
      aT '+'
abc
def
+++

```

The result of $\alpha_T \omega$ is an array for which the length of the first axis is the sum of the lengths of the first axes of α and ω , and all other axes are unchanged. For example:

```

      b←2 3P'uvwxyz'
      b
uvw
xyz
      P aT b
4 3
      aT b
abc
def
uvw
xyz

```

Similarly, the length of the last axis of α, ω is the sum of the lengths of the last axes of α and ω . All other axes are unchanged.

```

      P a, b
2 6

```

```

a,b
abcuvw
defxyz

```

Figure 5-12 illustrates ways in which dyad τ may be modified by the rank conjunction. The array *a* is the same as the *a* in the preceding figure, while *A* is an array of the same shape but containing capital letters. The default rank of τ is infinite, so (for these rank-5 arrays) $\tau^{\infty}5$ is no different than τ . The effect of specifying rank 4, 3, or 2 is illustrated. (In each of the three parts of Figure 5-12, the first box shows the expression executed, the next shows the shape of the result, and the last shows the resulting array.)

Using *on-rank-4* yields a result whose fourth-from-last axis is the sum of the lengths of that axis in the arguments. Similarly, *on-rank-3* affects the result's third-from-last axis, and *on-rank-2* affects the second-from-last. The same principle holds for *on-rank-1* (see Figure 5-13.), but joining-rank-0 produces a *new* axis in the result.

Joining Two Arrays Along a New Axis

When you join α and ω along an axis that already exists, you are said to *catenate* them. When you join them along a new axis, you are said to *laminare* them. Catenate and laminate do not refer to different verbs, but to different contexts in which τ or ρ are used.

To join two arrays along a new axis, they must have the same shape or one must be a scalar. (That is consistent with the general rule that arrays being joined have to have the same length along each axis except the one along which they are joined.)

Assuming that cells occupy the last axis, and all other axes are frame, you can make a new *last* axis by join-rank-0, thus:

```

'abc' ,∘0 'xyz'
≡≡
by
cz

```

In general, when you join two same-shape arrays by $\rho^{\infty}0$ or $\tau^{\infty}0$ (it does not matter which), the axes of the result are the (common) axes of α and ω , followed by 2.

There are several ways to join two arrays along a new *first* axis. Both ρ and τ create a new first axis when their arguments are items. Boxing the arguments causes them to be treated as items. For example:

[illegible]

Figure 5-12. Dyad τ rank 4, 3, and 2.

$\boxed{a \text{ } \tau^{\text{N}} 1 \text{ } A}$	$\boxed{2 \text{ } 2 \text{ } 2 \text{ } 2 \text{ } 4}$	\boxed{abAB}
		\boxed{cdCD}
		\boxed{efEF}
		\boxed{ghGH}
		$\boxed{\quad\quad}$
		\boxed{ijIJ}
		\boxed{klKL}
		$\boxed{\quad\quad}$
		\boxed{mnMN}
		\boxed{opOP}
		$\boxed{\quad\quad}$
		\boxed{qrQR}
		\boxed{stST}
		\boxed{uvUV}
		\boxed{wxWX}
		$\boxed{\quad\quad}$
		\boxed{yzYZ}
		$\boxed{\dots}$
		$\boxed{\dots}$
		$\boxed{\dots}$

Figure 5-13: Dyad τ rank 1.

'abc' , "< 'xyz'

abc

xyz

The above example applies < monadically to left and right cells. It then applies , to the results thus formed. Finally, the inverse of < (that is, >) is applied monadically to the results formed in the second step.

Or, writing the same thing another way:

> 'abc' > 'xyz'

abc

xyz

Another approach is to increase the rank of one of the arguments before you join them. For example,

```
>, < ω
```

gives ω a new first axis of length 1. (That is because $\langle \omega$ is an item, $, \omega$ is the ravel of that item and hence has one axis, and $>, \omega$ keeps that new frame-axis when opened.) Then:

```
'abc' ⍒ '>,'xyz'
```

```
abc
```

```
xyz
```

The monad τ turns a list into a one-column table. Applied to a list, that gives it a new last axis of length 1. If you then transpose it, the new axis is at the front.

```
'abc' ⍒⍒⍒ 'xyz'
```

```
abc
```

```
xyz
```

Joined Arrays May Differ in Rank by 1

When one of the arrays has rank 1 less than that of the other, it is treated as if it had an extra axis of length 1. The extra axis is a *leading* axis when the verb is τ and a *trailing* axis when the verb is $,$. For example, when you join a table and a list with τ , the list becomes a new row in the result; but when you join them with $,$ it becomes a new column. For example:

```
a ⍒ 'HIJ'
```

```
abc
```

```
def
```

```
HIJ
```

```
a, '12'
```

```
abc1
```

```
def2
```

Joining an Item to an Array

When one of the arrays is an item (with no axes), the item is replicated to match the lengths of all the axes *other than* the one along which joining occurs:

```
a ⍒ '*'
```

```
abc
```

```
def
```

```
***
```

When both arguments are lists, the distinction between τ and $,$ vanishes, since, with only one axis, the first axis is the last axis:

```
'abc'  $\tau$  'xyz'  
abcxyz
```

```
'abc' , 'xyz'  
abcxyz
```

When both arguments are items, the result is a two-item list. (In this case the result has a new axis that was not present in either argument before.)

Joining Modified by Bracket-Axis Notation

Early APL systems permitted certain verbs to be modified by a number in brackets placed after the verb. Because the bracket notation is inconsistent with the rest of APL syntax, this is now regarded as archaic. Nevertheless, to permit existing programs to continue to work without modification, it is still supported in APL. The verbs $,$ and τ are among those that can be so modified. In the expression

$\alpha, [k] \omega$

the value inside the brackets is a numeric item that identifies the axis along which the arguments are to be joined. Since it is an index, it is affected by the index origin $\square 10$. With the axis explicitly identified, $\alpha, [1] \omega$ has the same meaning as $\alpha \tau [1] \omega$.

As usual, the arguments are required to have the same length along the axes other than the axis along which they are to be joined. To join α and ω along axis 2, you write:

$\alpha, [2] \omega$

To use bracket-axis notation to join along a new axis, you identify the new axis by a fraction that lies somewhere between the existing axis numbers. For example, to join along a new axis to be placed between axis 2 and axis 3, you could write $\alpha, [2.5] \omega$. To join along a new axis to be created ahead of the first axis, $\alpha, [0.5] \omega$.³⁹ In a 0-origin context, the join could be written as $\alpha, [-0.5] \omega$.

³⁹ The fraction does not have to be 0.5; any fraction will do provided it differs by less than 1 from an existing axis number.

⊖ ⊕

Reverse, Upset; Rotate, Rowel

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
⊖	Reverse	Rotate	[none]	* * *
⊕	Upset	Rowel	[none]	* * *

The monads ⊖ and ⊕ reverse an array's major cells. The dyads ⊖ and ⊕ treat an array as a collection of lists and rotate each list by an amount specified in the left argument.

Monads ⊖ and ⊕

Monad ⊖, called *upset*, reverses the order of the major cells; that is, those at successive positions along the *first* axis. For example, when *t* is a table with three rows, ⊖*t* upsets the order of rows:

```

t←3 5⍴'One--Two--Three'
t
One--
Two--
Three

⊖t
Three
Two--
One--

```

Monad ⊕, called *reverse*, reverses the order of the 1-cells; that is, those at successive positions along the *last* axis. Monad ⊖ upsets (turns upside down) the order of occurrence of an array's major cells. There is a major cell corresponding to each distinct position along the first axis. In a table, the major cells are the rows of the table. In a rank-3 array, each major cell is a table. In a list, each major cell is an item.

For a rank-3 array *m* of shape 3-by-2-by-16, ⊖*m* upsets the order of the three tables, but leaves the order within each table unchanged:

```

m
aaaaaaaaaaaaaaaa
AAAAAAAAAAAAAAAA

bbbbbbbbbbbbbbbb
BBBBBBBBBBBBBBBB

cccccccccccccccc
CCCCCCCCCCCCCCCC

cccccccccccccccc
CCCCCCCCCCCCCCCC

cccccccccccccccc
CCCCCCCCCCCCCCCC

```

In similar fashion, monad ϕ reverses the order of the 1-cells. The location of last-axis cells in a table is illustrated in Figure 5-14.

t					ϕt				
Q	R	S	T	U	U	T	S	R	Q
V	W	X	Y	Z	Z	Y	X	W	V
A	B	C	D	E	E	D	C	B	A

Figure 5-14: Reversing the order of a table's last-axis cells.

In a rank-3 array, monad ϕ still reverses cells formed by splitting each position along the last axis. Figure 5-15 shows reversal of the array formed by:

`t←2 3 5p'AppleAvianAxon BasinBeechBroom'`

t					ϕt				
A	C	D	I	L	A	I	D	C	A
B	E	F	J	M	B	M	F	E	B
G	H	K	N	O	G	N	K	H	G
P	Q	R	S	T	P	T	R	Q	P
U	V	W	X	Y	U	Y	W	V	U

Figure 5-15: Reversing the order of last-axis cells in a rank-3 array.

Dyads ϕ and ϵ

The dyads ϕ and ϵ treat an array as a collection of lists. For each list in ω , α contains a number indicating the amount by which that list is to be rotated. The dyad ϕ , called *rotate*, rotates 1-cells of ω . It behaves as though it has right-argument rank 1. That is, it applies to lists spread along the *last* axis. Dyad ϵ , called *rowel*, does something similar, except that it applies to lists spread along the *first* axis. The symbols are chosen to suggest (at least for a table) the axis about which an array is rotated or reversed.

Each dyad produces a result that has the same shape as ω , with each list at the same location in the overall array. However, within each list, the sequence of items is rotated by an amount specified by an item in α which specifies by how much to rotate a list in ω .

α must be an array of integers. In general, it has rank 1 less than the rank of ω . It must have the same shape as ω for all axes *except* the axis along

which rotation takes place, or must be an item. Since dyad ϕ rotates the last axis, for ϕ , $(\rho\alpha)$ must equal $\neg 1 \div \rho\omega$. Similarly, since dyad θ rotates the first axis, for θ , $(\rho\alpha)$ must equal $1 \div \rho\omega$.

Each list being rotated is treated as a ring. It may be rotated any amount, any number of times. However, rotation by $\rho\omega$ simply brings the ring back to where it started, with no change. The effective amount of rotation is modulo the length of the list being rotated. For a seven-item list such as the following, rotation by $\neg 2$ is the same as rotation by 5:

```

      ^2\abcdfg
fgabcde

```

```

      5\abcdfg
fgabcde

```

The dyads ϕ and θ differ only in where in ω they find the lists that they rotate. ϕ rotates the 1-cells of ω ; that is, lists spread over the *last* axis. θ does the same thing, but to lists spread over the *first* axis. Applied to a rank-1 array, these are the same (since its first axis is also its last axis).

The name *rowel* for $\phi\omega$ is chosen by analogy with the toothed gear that by rotating raises or lowers a vertical bar. Applied to a table, dyadic θ requires a left argument list containing an item for *each column* of ω . Consider the following 7-by-20 table called *Chart* (shown horizontally double-spaced so that the amount of rotation can be shown for each column):

Chart

```

. . . . .
* * * * *
■ ■ ■ ■ ■
. . . . .
. . . . .

```

Each column can be rotated independently. For example:

```

0 0 1 1 2 2 3 1 0 ^2 ^1 0 0 1 1 2 2 3 3 2\Chart
. . . . .
. . . . .
. . . . .
. . . . .
. . . . .
. . . . .
. . . . .

```

In general, the left argument α must contain an item for each of the first-axis lists of ω , so the shape of α is $1 \uparrow \rho \omega$. However, when α contains a single item, it is applied to all the lists in ω :

1 ⌷	⌷ 1
Two--	Three
Three	One--
One--	Two--

⌷ and ⌸ Modified by Bracket-Axis

As monads, \uparrow and \downarrow are concerned with reversing cells identified by positions along one axis (the last or the first). As dyads, \uparrow and \downarrow are concerned with rotating each of a set of lists located at positions along one axis (the last or the first). \uparrow takes lists from the last axis, and \downarrow from the first.

The ISO standard for APL permits you to identify some axis other than the first or last, by using brackets. Although bracket-axis notation is now considered obsolescent (because the rank conjunction perhaps combined with transpose now provides a more general and consistent way to achieve the same ends), to permit existing programs to run without modification, APL continues to support the use of brackets as a conjunction specifying the axis along which reversal or rotation take place, like this:

$\alpha \uparrow[k] \omega$
 $\alpha \downarrow[k] \omega$

Since the axis of effect is expressly identified by the value in the brackets, there is no difference between $\uparrow[k]$ and $\downarrow[k]$. The value inside the brackets must be an integer item and must be a member of $1 \uparrow \rho \omega$ (and therefore is dependent of the value of the system noun $\Omega 10$). α must have rank 1 less than the rank of ω and shape $(k \in 1 \uparrow \rho \omega) / \rho \omega$.

Upset and Rowel in Terms of Rotate and Reverse

\uparrow can be defined in terms of \uparrow by the identities:

$\uparrow \omega \iff \uparrow^{\uparrow} \uparrow \omega$
 $\downarrow \omega \iff \downarrow^{\downarrow} \downarrow \omega$

Transpose; Cant

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
Ω	Transpose	Cant	[none]	∞ * *

The verb Ω permutes the order of the axes of an array.

- The left argument of the dyad $\Omega\omega$ specifies how the axes are to be permuted. By your choice of left argument, you may also cause certain axes to be mapped together to take a *diagonal slice* through ω .
- The monad $\Omega\omega$ reverses the order of the axes of ω .

$$\Omega\omega \iff (\Phi 1PP\omega)\Omega\omega$$

When ω is a *list* (having only one axis) or an *item* (having no axes), the result of $\Omega\omega$ is ω .

Monad Ω

When ω is a *table* (rank-2), the result has rows where ω has columns and columns where ω has rows:

ω	$\Omega\omega$
Copenhagen	CLL
Libreville	oIU
Luxembourg	pbx
	ere
	mm
	hvb
	aIo
	glu
	eIr
	neg

The shape of the result of transpose is the reverse of the shape of ω .

$$P\Omega\omega \iff \Phi P\omega$$

Thus, transposing a rank-3 array moves ω 's last axis (columns) so that it becomes the first axis (planes) of the result. When ω is the 2-by-3-by-6 array shown at the left, $\Omega\omega$ is the 6-by-3-by-2 array at the right:

ω		$\alpha\omega$

	ts	
	dg	
	el	
	ac	
	ou	
	nn	
	wo	
	ns	
	ww	
	aw	

Dyad α

The dyadic form of α permits you to permute the axes of ω or to map two or more axes together so as to select a diagonal section of ω .

α is a list of integers that tell APL what to do with each of the axes of ω . α must contain one element for each axis of ω .³⁰ Transposition has no effect unless ω has at least two axes.

The positions within α correspond to the various axes of ω . That is, position 1 within α describes what is to be done with axis 1 of ω , and so on.

The values within α refer to the axes of the result. Since axes are numbered starting from $\Omega 10$, the values in α must reflect the current index origin.

The result can have any rank not greater than the rank of ω . Suppose the desired result rank is called r . Then the numbers in α must be chosen such that α includes each member of $1:r$ at least once. For example, when you want a rank-3 result, $1\ 3\ 2\ 1$ is a permissible value for α , whereas $1\ 4\ 3\ 4$ is not (because it omits 2).

The result returned by $\alpha\omega$ is an array formed by permuting or mapping together the axes of ω . The result contains one axis for each unique number in α . When α contains no repetitions, the rank of the result is the same as the rank of ω . Suppose $z \leftarrow \alpha\omega$, then:

³⁰ When ω has rank 1, the system also accepts an atom for α where, strictly speaking, it should require a one-element list.

$$p\omega \iff (pz)[\alpha]$$

$$pz \iff (p\omega)[\alpha] \quad \text{When the items of } \alpha \text{ are distinct.}$$

Transpositions that Retain All the Axes

When the numbers in α are distinct, all axes of ω are included in the result; only their order is changed. Figure 5-16 illustrates how the axes are rearranged.

Figure 5-16: Axes of argument and axes of the result.

Suppose ω has 4 axes. Then the expression

$3\ 1\ 4\ 2\ \text{⌊}\omega$

says that axis 1 of ω becomes axis 3 of the result;
axis 2 of ω becomes axis 1 of the result;
axis 3 of ω becomes axis 4 of the result;
axis 4 of ω becomes axis 2 of the result.

When α is a list of consecutive integers in ascending order, the axes are returned in the same positions they had before, and so:

$(1\text{pp}\omega)\text{⌊}\omega \iff \omega$

When the left argument contains consecutive integers in *reverse* order, the sequence of the axes of ω is reversed, which is the same as the result of monadic transpose:

$(\phi 1\text{pp}\omega)\text{⌊}\omega \iff \text{⌊}\omega$

Figure 5-17 illustrates transposition with a specific example, using a rank-4 array whose shape is 2-by-3-by-3-by-2, so that you can trace the relocation of the axes and of each of the items.

Figure 5-17: Dyadic transpose of a rank-4 array.

Figure 5-18 depicts ω and part of its transpose, showing how the first plane of the first block of the result receives elements from ω . ω is depicted as two blocks of tables, each containing three tables.

Figure 5-18: Visualization of a rank-4 array and its 3 1 4 2 transpose.

Diagonal Slices

When α contains repetitions, the number of distinct numbers in α is less than the rank of ω , so the rank of the result is also less than the rank of ω . Consider what happens when ω has rank 4, but α is 1 3 2 3, as in the examples in Figure 5-19 and Figure 5-20. The value 3 occurs both at position 2 and at position 4. Axis 3 of the result is to be formed from both axis 2 and axis 4 of ω . Two distinct axes of ω are mapped into a single axis of the result.

That is done by taking an item from ω only when its position is the same on both axes.

Figure 5-19: Axes mapped together during transpose.

Figure 5-20: Visualization of 1 3 2 3 transpose.

By mapping axes together, you are *selecting a diagonal*. For a 4-axis array ω , the expression

$$1\ 1\ 1\ 1\ @\ \omega$$

gives you the list formed by

$$\omega[1;1;1;1], \omega[2;2;2;2], \omega[3;3;3;3] \text{ and so on.}$$

Similarly, for a table ω , the transpose $1\ 1@ \omega$ gives you a list from the main diagonal.

When the axes mapped together differ in length, the number of positions common to both axes is only as great as the length of the *shortest* axis. For example, when ω has shape 3 10, the expression $1\ 1@ \omega$ selects only the elements that in Figure 5-21 are shown shaded.

Figure 5-21 : A diagonal is confined to the length of the shorter axis.

Figure 5-22 and the next two figures illustrate several types of diagonal slices taken from a rank-3 array.

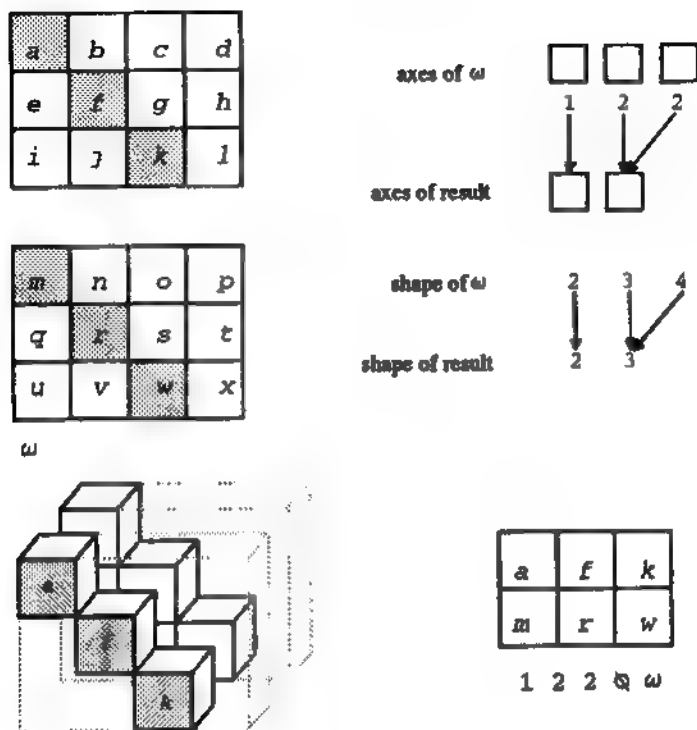

Figure 5-22: Mapping produced by 1 2 2 transpose of a rank-3 array.

Figure 5-23: Mapping produced by 1 1 2 transpose of a rank-3 array.

Figure 5-24: Mapping produced by 2 1 2 transpose of a rank-3 array.

↑ ↓

Raze; Take, Drop

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
↑	[none]	Take	[none]	* * *
↓	Raze	Drop	[none]	∞ * *

The monad \downarrow (raze) reconstitutes arrays by assembling the opened elements of the array along the leading axis.

The dyads \uparrow (take) and \downarrow (drop) construct an array by selecting a segment along each of the axes of ω . The left argument α is a list that specifies for each axis of ω the length of the segment to be selected.

Monad \downarrow

Raze opens each item along the leading axis of its argument, catenates those items along the first axis, and boxes them again. Raze is useful for reconstituting data that were separated by the cat conjunction. (See Chapter 6, "Adverbs and Conjunctions" for the definition of cat.) Consider the word processing problem of replacing all occurrences of one word by another in a text vector. This might be achieved by cutting the text into words, boxing each word, finding the words of interest, replacing them, and then using raze to paste the words back together into a vector:

T4T2<This and that and these and those.

This	and	that	and	these	and	those.	

T4T[(T=0<'and ')/1PT]<'or '

This	or	that	or	these	or	those.	

>+T
 This or that or these or those.

When raze is applied to open arrays, the result is boxed as well:

```

fatso
oher
beets

↓m
|_fob_|_ace_|_the_|_set_|_ors_|

```

When raise is applied to items, the result is the enclosed item.

Operation along other axes can be achieved with the rank conjunction.

Raze of Empty Arrays

Because `raze` removes elements from the shape vector, it can create non-empty arrays from empty ones. If the leading axis of the argument is of length 0, the result of `raze` has shape `1+Pw`. The result is filled with the box fill element.

Raze Along Unit Axis

Raze applied to an argument ω that has length 1 along its leading axis produces a result of shape $1 \times p \times \omega$, formed by boxing each item in the argument.

Dyad ↑ and ↓

The dyad *take* describes the result by specifying the segments of ω to be included in the result. The dyad *drop* specifies the segments of ω to be excluded, so that the result is formed from those that remain.

The result always has the same rank as ω (except when ω is an item). Each value in α specifies the length of a segment along the *corresponding axis* of ω to be included in or excluded from the result. For example, when ω is a rank-3 array, the expression

$2\ 3\ 4\ \uparrow\ \omega$ returns

the first 2 positions along ω 's first axis;
the first 3 positions along ω 's second axis;
the first 4 positions along ω 's third axis.

Drop works in a similar manner, except that it omits, or drops, the specified number of items along each axis:

$2\ 3\ 4\ \downarrow\ \omega$ returns

all but the first 2 positions along ω 's first axis;
all but the first 3 positions along ω 's second axis;
all but the first 4 positions along ω 's third axis.

A *negative value* in α refers to the *last* positions along an axis. For example, the expression

$2\ \bar{3}\ 4\ \uparrow\ \omega$ returns

the first 2 positions along ω 's first axis;
the *last* 3 positions along ω 's second axis;
the first 4 positions along ω 's third axis.

Again, drop behaves similarly to take with a negative values:

$2\ \bar{3}\ 4\ \downarrow\ \omega$ returns

all but the first 2 positions along ω 's first axis;
all but the *last* 3 positions along ω 's second axis;
all but the first 4 positions along ω 's third axis.

- α may contain *fewer* elements than the rank of ω ; in that case, degenerate rules apply, described below.
- α may never contain more elements than ω has axes, except in the special case when ω has *no* axes, discussed below.
- α may be an item. In that case it is treated as though it were a one-item list.

See Figure 5-25 for examples of the operation of take and drop.

Figure 5-25: Take and drop.

Take with Short Left Argument

When α has fewer elements than ω has axes, α describes how much to take of the leading axes of ω , while the remaining axes are returned entire. Thus, for any array ω have any rank 2 or higher, the phrase

$2 \ ^3 + \omega$ returns

the first 2 positions along ω 's first axis;
the last 3 positions along ω 's second axis;
all positions along any remaining axes.

Similarly, the expression $2 + \omega$ returns

the first 2 positions along ω 's first axis;
all positions along any remaining axes.

And, by a logical progression, $1 + \omega$ returns all of ω .

In general, the effect of a short left argument is:

$$\alpha + \omega \iff (\alpha, (\rho, \alpha) + \rho\omega) + \omega$$

Drop with Short Left Argument

When α has fewer elements than ω has axes, α describes how much to drop from the leading axes of ω , while the remaining axes are returned without dropping anything. Thus, for an array ω of any rank 2 or greater, the expression

$2\ 3\omega$ returns

all but the first 2 positions along ω 's first axis;
all but the first 3 positions along ω 's second axis;
all positions along any remaining axes.

Similarly, the expression 2ω returns

all but the first 2 positions along ω 's first axis;
all positions along any remaining axes.

And by a logical progression 1ω returns ω .

In general, the effect of a short left argument is:

$$\alpha\omega \iff ((p\omega)\uparrow\alpha)\omega$$

Dropping More Elements than Exist

When α includes an element whose magnitude is greater than the length of the corresponding axis of ω , you are in effect asking to drop more elements than exist along that axis. In the result, the length of that axis is 0; the excess value in α has no effect. Thus:

```

4 6
    p3 2ω
1 4
    p5 2ω
0 4

```

Over-Take and Padding

When the magnitude of an element of α is greater than the length of the corresponding axis of ω , you are in effect requesting to take from ω more elements than exist along that axis. The result nevertheless contains as many positions as you request. The additional positions contain a fill value, which is:

0 when ω consists of numbers.
 ' ' when ω consists of characters.
 <10 when ω consists of boxes.

Where an "oversize" element of α is *positive*, the result contains as many elements as are available in ω , followed by the fill value for the remaining positions, so that the fill values (if any) appear at the *end* of that axis.

Where an oversize element of α is *negative*, elements are taken from the *end* of that axis of ω and placed at the end of the corresponding axis in the result. The fill value appears in the extra positions at the *front* of that axis. Suppose ω is the following 3-by-4 table of numbers:

```
1  2  3  4
5  6  7  8
9 10 11 12
```

```
          5 -7 +6
0  0  0  1  2  3  4
0  0  0  5  6  7  8
0  0  0  9 10 11 12
0  0  0  0  0  0  0
0  0  0  0  0  0  0
```

Take When the Right Argument Is Empty

When α calls for creation of a non-empty array but ω is empty, the result contains only fill values. Then the result has the same internal type as the right argument.³¹ Although in general the type of an empty array is not significant, information regarding its type is retained and does affect the result produced by take (and also by the derived verb *expand*; see Chapter 6, "Adverbs and Conjunctions").

Type of empty right argument: *character* Result: blanks.

Type of empty right argument: *numeric* Result: zeros.

Take and Drop Applied to Item α

When ω is an item (having no axes), but α is not empty, APL treats ω as if it had the rank implied by the length of α and every axis had length 1. Thus:

```
          3 -7 + 6
0  0  0  0  0  0  6
0  0  0  0  0  0  0
0  0  0  0  0  0  0
```

³¹ Note that an empty array is either numeric or character; the value of an empty array descended from an array of boxes is numeric.

$p3 \leftarrow 7 + 6$
 0 0

Take and Drop Modified by the Rank Conjunction

The rank conjunction specifies the number of axes in an argument cell. Any leading axes left over are frame axes. When the rank conjunction modifies \uparrow , α applies not to ω as a whole, but to each cell within ω . Thus, the effect of the expression

$2 \ 3 \uparrow \omega \ 1 \ 2 \ \omega$

is to take for each cell the first 2 positions along the cell's first axis and the first 3 positions along the cell's second axis. The frame axes are reproduced in the result. Thus, in general:

$$\alpha \uparrow \omega(1, k) \ \omega \iff ((-k) + \rho\omega), \alpha \uparrow \omega$$

Similarly, when $k \neq 0$:

$$\alpha \uparrow \omega(1, k) \ \omega \iff ((-k) + 0 \times \rho\omega), \alpha \uparrow \omega$$

When take is applied with rank 0, each result cell has a new axis for each item in α . In that case, the shape of the result is given by:

$$\rho \alpha \uparrow \omega \ 1 \ 0 \ \omega \iff (\rho\omega), |\alpha$$

And the result is:

$$\alpha \uparrow \omega \ 1 \ 0 \ \omega \iff ((\rho\omega), |\alpha) \rho\omega, \omega \ 0 \ 1 \ (\times / |\alpha) \rho 1 + 0 \rho\omega$$

Grade up, Grade down

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
	(Numbers)	(Characters)		
Δ	Grade up	Grade up	[none]	∞ ∞ ∞
∇	Grade down	Grade down	[none]	∞ ∞ ∞

Grade returns a list of integers which if used to select the major cells of ω would arrange them in order. The result has the same length as the first axis of ω . The argument must have at least one axis. The result is a *permutation vector*, since it contains each of the first $1 + p\omega$ integers exactly once. Since the values are indexes, the result is sensitive to $\square 10$.

The verb Δ returns the indexes that would arrange the major cells in *ascending order*, while ∇ returns the indexes that would arrange them in *descending order*. Cells that have equal values are left in the order in which they occur in ω . Thus, Δ and ∇ are said to be *stable*.

Monads Δ and ∇

The monads Δ and ∇ are defined for real numbers. Complex numbers have no unambiguous sequence and hence are outside the domain.

The dyads Δ and ∇ are defined only on characters. Characters have no inherent collating sequence, so α describes the sequence to be used.

The result of any of these verbs is the list of indexes that would sort the major cells of ω . When ω is a list, each major cell is an item, and the result of *grade* is the list of indexes that would sort the items. For example:

```
List←1.2 1.1 1.2 1.4 1.1
ΔList
2 5 1 3 4

List[ΔList]
1.1 1.1 1.2 1.2 1.4

∇List
4 1 3 2 5

List[∇List]
1.4 1.2 1.2 1.1 1.1
```

When you grade an array that has more than one axis, the result is still a list of indexes for the *major* cells. The cells are graded by assigning to each cell a numeric value equal to the base value of all the items in the cell, taking them in ravel order (see the definition of *, (ravel)*). The base value is evaluated using a radix larger than the value of any of the individual items. That is equivalent to saying that the cells are graded so that the left-most item in the ravel of the cell has greatest weight. For example:

Table

```
1 4 9 2.1
2 0 0 1.8
1 9 3 0
1 7 7 6
```

⍤Table

```
1 4 3 2
```

Table[⍤Table;]

```
1 4 9 2.1
1 7 7 6
1 9 3 0
2 0 0 1.8
```

Table[▽Table;]

```
2 0 0 1.8
1 9 3 0
1 7 7 6
1 4 9 2.1
```

Grade is Not Tolerant

Grade is *not* affected by `⌊ct`, comparison tolerance. This is because the monad grade depends upon the transitivity of *greater* or *smaller*, but tolerant comparisons are not transitive.

Since grade is not tolerant, it is possible for grade to reverse the order of two cells even when the cells are reported as equal when compared by the tolerant relation = under non-zero values of `⌊ct`.

Dyads ⍤ or ▽ Grade Character Arrays

To grade character data, you must provide a collating sequence as the left argument of `⍤` or `▽`. APL has no inherent collating sequence for characters. `α` assigns a numeric value to each of the characters in `ω`. With those values, the major cells are graded in the same way as a numeric array.

When the collating sequence α is a list, the value assigned to each character in ω is $\alpha\omega$, so:

$$\alpha\omega \Leftarrow \Delta\alpha\omega$$

When ω contains a character that appears nowhere in α , it gets a value greater than the value of any of the characters that are present (just as $\alpha\omega$ returns \square for an item of ω that is not present in α).

```

Collating Sequence with Tied Weights

When the material to be sorted contains both lowercase letters and capitals, what is to be done? Schemes such as *Alf1* and *Alf2* include both but do not lead to satisfactory alphabetization. (See Figure 5-26.)

The heart of the matter is that a one axis alphabet such as *Alf* has no way to give two characters the same weight. There is no way to put two characters at the same position. The problem is solved by using as many axes as necessary to accommodate sets of characters that are tied.

Suppose you want to place *b* and *B* after *a* or *A* and before *c* or *C*. A simple way to achieve the desired sort is to use a collating sequence with two axes, such as *Alf3*:

```
'*',Alf3
```

```
* abcdefghijklmnopqrstuvwxyz  
* ABCDEFGHIJKLMNOPQRSTUVWXYZ
```

(The * is there so you can see that the first position is blank.)

Where α has more than one axis, the dominant consideration is the position at which a character is found along the *fast* axis of α . (In a table, which column it is in.) In *Alf3*, both *b* and *B* are at column 3.

Figure 5-26: Effects of alternative left arguments to grade.

A character's location on the other axes contributes to the result only to break a tie between words that otherwise would have the same weight. The next-to-last axis breaks a tie on the last axis; the axis before that breaks a tie on the last two, and so on. To see the effect of this rule, compare the ordering produced by the tabular alphabet A1f3 with the ordering produced by the single axis alphabet A1f1. The list of words to be ordered is taken from the paper by Howard J. Smith, who first proposed the rules for alphabetic grade.³²

Characters with Identical Weights

The table A1f3 provides that *b* or *B* comes after *a* or *A* and before *c* or *C*. Wherever there is a tie, a word that contains *b* always precedes a word that contains *B*. However, it is possible to construct the left argument so that certain letters have identical weights, and thus words that differ only in those letters are unaffected by grading.

For two characters to have identical weight, they must have the same effective position in α . When the same character occurs at two or more positions in α , that character's effective position is at the minimum of its various coordinates. For example, if the letter *S* occurs at row 1, column 40 and also at row 5, column 13, then its effective position is 1 40 15 13; that is, row 1, column 13. The letter *S* then has identical weight to a unique character located at row 1, column 13, or to any character that occurs twice, both in row 1 and a higher row, and in column 13 and a higher column.

To give capital and lowercase letters identical weight in sorting, one set (for example, the lowercase letters) is usually placed at the top left corner of the alphabet table, while the other set is duplicated, both to the right and below, as illustrated below.

```
abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ
ABCDEFGHIJKLMNOPQRSTUVWXYZ
```

In such a table, the effective weight of *a* is exactly the same as the effective weight of *A*. See Figure 5-27.

Figure 5-27: Effective weight of characters occurring twice in α .

ρ

Shape; Reshape

	Monad	Dyad	Identity Element	Argument Rank
ρ	Shape	Reshape	[none]	∞ * *

The symbol ρ (rho) denotes the verbs *shape* or *reshape*.

- The monad $\rho\omega$ returns the shape of ω .
- The dyad $\alpha\rho\omega$ (" α reshape of ω ") creates an array whose shape is α and whose items are taken from ω .

Monad ρ

The monad $\rho\omega$ ("shape of ω ") returns the length of each of the axes of ω . The result is a list of (non-negative) integers. Since it contains one element for each axis of ω , the number of elements returned tells you the rank of ω . The value of each element is the length of the corresponding axis of ω . When ω has no axes, the result is a list containing *no* items (an empty list). For example:

```

       $\omega \leftarrow 2 \ 3 \ 0 \ 1 \ 6$ 
       $\rho\omega$ 
2 3
       $\rho\rho\omega$ 
2

```

```

      ω←15
      ρω
5
      ρρω
1
      ω←6
      ρω
[Empty list displays as blank line.]
      ρρω
0

```

Dyad ρ

The left argument α is a list of non-negative integers specifying the length that each axis is to have in the resulting array. APL accepts an item as equivalent to a one-element list.

The right argument ω is an array of any type or shape. However, ω may be an empty array only when the new array is empty also (that is, when α contains a zero). APL rejects an attempt to create a non-empty array from an empty array with the message *length error*.

The expression $\alpha\rho\omega$ returns an array whose shape is α and whose items come from ω . The positions in the result are filled by taking the elements of ω in *row-major* order. Row-major order describes the sequence in which items in an array are considered. Referring to a table, it means that you take all the items in the first row before you go on to the next row. More generally, for an array of any rank, you step through the positions along the *last* axis, then along the *next to last*, and so on. This is the same order as produced by the APL verb *ravel*, so that:

$$\alpha\rho\omega \longleftrightarrow \alpha\rho,\omega$$

In $\alpha\rho\omega$, when α asks for *fewer* items than there are in ω , items are taken from ω in row-major order until the result is complete; any remaining items of ω are ignored.

When α asks for *more* items than there are in ω , the items of ω (always in row-major order) are repeated cyclically in the result. For example, suppose ω is a 2-by-5 table containing the following values:

```

0 1 2 3 4
5 6 7 8 9

```

Then a result containing *fewer* items than ω might be obtained as follows:

7pw
0 1 2 3 4 5 6

Or by:

2 4pw
0 1 2 3
4 5 6 7

A result requiring *more* items than there are in ω might be obtained as follows:

12pw
0 1 2 3 4 5 6 7 8 9 0 1

Or by:

3 7pw
0 1 2 3 4 5 6
7 8 9 0 1 2 3
4 5 6 7 8 9 0

Note that if α is a list longer than $\rho\omega$ but ending in $\rho\omega$, the effect is to replicate ω completely at each of the positions along the new axes. For example:

$\rho\omega$
2 5

3 2 5pw
0 1 2 3 4
5 6 7 8 9

0 1 2 3 4
5 6 7 8 9

0 1 2 3 4
5 6 7 8 9

If the shape of the result differs from the shape of the right argument, a systematic pattern may be generated. For example:

4 4P5+1
1 0 0 0
0 1 0 0
0 0 1 0
0 0 0 1

The shape of a single item (a scalar) is empty. To generate an item with dyad P , the left argument α must be empty:²²

```
(10)pw
```

The shape of the result produced by reshape matches the value of α . The only exception is that APL tolerates a scalar α for a one-element vector. Thus:

```
papw  $\Leftrightarrow$  , $\alpha$ 
```

and

```
(pw)pw  $\Leftrightarrow$   $\omega$ 
```

∈

Member

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
∈	[none]	Member	[none]	* 0 ∞

For each item (that is, each number, character, or box) within α , the expression $\alpha \in \omega$ reports whether a matching item can be found anywhere in ω . The shape of ω does not matter, nor does the position in ω at which a matching item is found.

The result is a Boolean array having the same shape as α , with a 1 for each item in α that is matched somewhere in ω , and a 0 for each item that is not.

```
List←2 3 5
```

```
⌈Table←2 3⍲1 2 3 4 5 6
```

```
1 2 3
```

```

```
List ∈ Table
```

```
1 1 1
```

```
Table ∈ List
```

```
0 1 1
```

```
0 1 0
```

²² For most purposes, the type of an empty array is immaterial, so ${}^*{}^*pw$ works equally well.

Items with different levels of boxing never match. For example, if you ask whether the numbers in the open list 1 2 3 are members of an array of boxes, the answer is "no" even when those values are inside the boxes:

```
1 2 3 ∈ (<1 2 3 4),<'abcd'
0 0 0
```

Similarly, a singly enclosed box is not a member of a doubly enclosed box:

```
((<'abc'),<'def') ∈ (<<'abc'),<<'def'
0 0
```

Membership Modified by the Rank Conjunction

The rank conjunction ω may organize the frame in which membership in a cell of ω is returned. For example, suppose n is a seven-item list of numbers and T is a nine-row table. (It does not matter how many columns T has.) Then

```
      n
69 3 5 4 8 6 2

      T
7 0 4
6 9 1
1 6 7
1 4 1
5 7 6
0 9 6
1 7 5
8 0 8
3 1 8
```

```
      nωT
0 1 1 1 1 1 0
```

returns a result-frame of rank 1. Within that frame, there are seven cells, each containing a 1 or a 0, showing whether an element of n exists somewhere in T .

By contrast,

```
      n ∈ω1 T
0 0 0 1 0 0 0
0 0 0 0 0 1 0
0 0 0 0 0 0 1 0
0 0 0 1 0 0 0 0
0 0 1 0 0 1 0 0
0 0 0 0 0 1 0
```

```

0 0 1 0 0 0 0
0 0 0 0 1 0 0
0 1 0 0 1 0 0

```

says you should consider rank-1 cells from *both* arguments. For n , that means the entire array is a single cell, so n has an empty frame.

For T , that means each row is a cell. There is a frame axis of length 9 (that is, the number of rows that T has).

Since one argument has an empty frame and the other has a length-9 frame, the result has a length-9 frame. As usual, the empty frame is paired with each of the cells in the other argument. So the first cell of the result is formed from $n \in T[1;]$, the second from $n \in T[2;]$, and so on. Each of those produces a seven-item cell. The cells fit into the length-9 frame, so the result has shape 9-by-7.

⊆

Find, In

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
⊆	[none]	Find, In	[none]	* ∞ ∞

Dyad ⊆

The dyad \subseteq (*in*, also known as *string search* or *find*) locates all occurrences of one array within another. For an array ω and a pattern array α , the statement

$$b \leftarrow \alpha \subseteq \omega$$

produces a Boolean array b such that the 1s in b mark the *beginning points* of the pattern α in ω . The beginning points are the first element of a list, the upper left-hand corner of a table, and so on for higher-dimension arrays. The array b has the same shape as ω . Both α and ω can be arrays of any **rank**.

In can be defined in terms of the *3-cut* of "A Dictionary of APL" as follows:

$$\alpha \subseteq \omega \equiv ((\Omega 1, \top \rho \alpha) \ 3 \circ \omega) \in \alpha$$

In can be used in string searching as follows:

```

      'to'g'Onto Toronto, pronto,Tonto!
0 0 1 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 1 0 0 0 0 0 1 0 0

      (2 2p'toTo')gV1 'Onto Toronto, pronto,Tonto!
0 0 1 0 0 0 0 0 0 0 1 0 0 0 0 0 0 0 1 0 0 0 0 0 1 0 0
0 0 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 0 0 0 0 0

```

In can be used to remove multiple blanks from a string T using the expression $(\sim' \text{'gT})/T$.

In can be used for pattern finding in higher-rank arrays as well, lending itself to image analysis and similar applications:

```

      rpat←2 3p1 2 3 2 3 4
1 2 3
2 3 4
      +image←5 5p14
1 2 3 4 1
2 3 4 1 2
3 4 1 2 3
4 1 2 3 4
1 2 3 4 1
      patgimage
1 0 0 0 0
0 0 0 0 0
0 0 1 0 0
0 1 0 0 0
0 0 0 0 0

```

1

iota; Count, Indexof

	<i>Monad</i>	<i>Dyad</i>	<i>Identity Element</i>	<i>Argument Rank</i>
ι	Iota; Count	Indexof	[none]	* * *

The symbol ι is the Greek letter *iota*. *Monad* ι generates *consecutive integers*. *Dyad* ι returns *index numbers*: that is, the locations in α at which the items of ω are found.

Monad ι

The monad ι "counts" in the sense that ιn returns a list of the first n integers. The first counting number is either 1 or 0, as set by the system noun $\Omega 10$, *index origin*.

```
      15 - $\Omega 10$  1
1 2 3 4 5
```

```
      15 - $\Omega 10$  0
0 1 2 3 4
```

Moreover, for a list L ,

```
 $\iota PL$ 
```

is the index for each of the items in L , so that

$$L \iff L[\iota PL]$$

Default Rank of Monad ι

Monad ι expects a single integer as its argument. If you impose argument rank-0, you can generate several sets of consecutive integers.

For consistency with existing applications, APL treats monad ι as though its usual argument is a list, even though that list may only contain one number. Having a rank-1 argument is handy in expressions such as $A[\iota PB]$.

Forcing argument rank-0 permits a table result, thus:

```
      1 $\overline{0}$  5 5
1 2 3 4 5
1 2 3 4 5
```

But it also gives a table result in contexts where you may not want it, for example to generate a list of indexes.

Dyad ι

Dyad ι (*indexof*) maps the *value* of each item in ω to an *index* that identifies a location in α . The expression $\alpha \iota \omega$ returns a result that indicates where in the list α each of the items of ω may be found. For example:

```
      a←'abcdefghijklmnpqrstuvwxyz'
      a $\iota$ 'cat'
3 1 20
```

ω may be of any rank or shape. The result has the same rank and shape as ω . For example:

```

       $\omega$ 
2 3
   b
fat
cat
      ab
6 1 20
3 1 20

```

α must be a list, so that a single index is sufficient to identify a location within α .

The result is dependent on Ω io. For example:

```

      at'cat'  $\leftarrow$   $\Omega$ io+1
3 1 20

      at'cat'  $\leftarrow$   $\Omega$ io+0
2 0 19

```

For an item in ω that does not occur in α , `indexof` returns Ω io+ $\rho\alpha$.

For an item in ω that occurs more than once in α , `indexof` returns the index of its *first* occurrence in ω . This is exploited in a common phrase for computing the *nub* (that is, the unique members) of a list:

```
((\PList)=List\List)/List
```

For an item that is duplicated in *List*, the first occurrence has an index equal to its position. However, later occurrences also have that same index, which therefore must be different from the corresponding member of *PList*, resulting in their exclusion from the nub. Nub can be more tersely defined using *nubsieve*, as $(\#w)/w$.

Tolerant Comparison in Dyad \vee

The expression $\alpha\vee\omega$ asks, in effect, for the index of the first item in α that *matches* an item in ω . *Match* is affected by comparison tolerance, Ω ct. Strictly speaking, `indexof` returns the first location in α that is *tolerantly equal* to an item in ω . (See the discussion of tolerant comparison in the description of $=$ earlier in this chapter)

Comparison tolerance can have no effect on the result of `indexof` or membership when the arguments are characters or integers in the range -2^{31} to $2^{31}-1$. However, it may indeed affect both the results and the time required to compute them for fractional or complex values.

$\alpha[\omega]$

Bracket Indexing

The expression (or expressions) enclosed in square brackets selects items from within the noun α , which may be any array having at least one axis.

Bracket indexing is anomalous in several respects. Unlike other APL verbs, indexing is indicated not by a single symbol but by a pair of symbols. In some respects the left bracket [is the primary symbol, while the right bracket] serves to delimit the right argument. Delimiting the argument implies an *order of execution*, like putting parentheses around the entire indexed expression:

$$a[i] + b \iff (a[i]) + b$$

The brackets surround not an expression but a set of independent expressions, one for each axis of α . To select from an array whose rank is greater than 1 requires more than one index expression; the various expressions are separated from each other by semicolons. When α is a list, one expression suffices to specify positions within it. This is written:

$$\alpha[\omega]$$

When α is a list, bracket indexing is inverse to dyadic iota. For an array x (of any rank) all of whose items are contained somewhere in α :

$$x \iff \alpha[\alpha \backslash x]$$

However, when α is an array of rank 2 or greater, using bracket indexing to select a sub-array from within it requires a separate expression for each of α 's axes. These expressions are separated by semicolons, and the set of expressions for all of α 's axes is surrounded by brackets. The number of semicolons is therefore one less than the rank of α . For example:

$$\text{When } \alpha \text{ is a table: } \alpha[\omega_1; \omega_2]$$

$$\text{When } \alpha \text{ has rank 4: } \alpha[\omega_1; \omega_2; \omega_3; \omega_4]$$

Figure 5-28 illustrates the use of bracket indexing to select an item from an array.

Figure 5-28: Expression to select an item from a rank-3 array.

Shape of the Result Produced by Bracket Indexing

The result of $\alpha[\omega_1; \omega_2; \dots]$ is an array formed by selecting items from α at the positions indicated by the values in ω_1, ω_2 , etc. Each of the index expressions $\omega_1 \dots \omega_n$ may be of any rank or shape, provided only that every one of its elements is a valid position within the corresponding axis of α (subject to the visible value of the index origin $\square i o$). The shape of the resulting array is found by concatenating the shapes of the indexes for each axis; that is:

$$\rho \alpha[\omega_1; \omega_2; \dots; \omega_n] \Leftarrow (\rho \omega_1), (\rho \omega_2), \dots, (\rho \omega_n)$$

The symbol $;$ is punctuation. It is a delimiter, not a verb. Writing $\omega_1; \omega_2$ does *not* form a single array from ω_1 and ω_2 . You cannot write a general expression such as $\alpha[\omega]$ that will be valid regardless of the rank of α . In fact, $\alpha[\omega]$ is valid only when α is a list (since it contains zero semicolons), and $\alpha[\omega_1; \omega_2]$ is valid only when α is a table (because it contains one semicolon), and so on. The semicolon acts as an absolute separator in these expressions, so you do *not* need to enclose the various expressions for each axis in parentheses (even when they are compound expressions).

To write a program that can index an array of any rank, you must either generate a character expression containing the correct number of brackets and semicolons and then execute it with α , or else index it by referring always to the ravel of the array, exploiting an identity mentioned below.

Keeping All Positions Along an Axis

You can retain *all* positions along a particular axis of α by *not* selecting along that axis. You do that by writing *no* expression for that axis at the appropriate position between brackets. That axis is then reproduced unchanged in the result.

For example, when α is a list, the result of $\alpha[]$ is α .

When α has three axes, then $\alpha[\omega_1; \omega_2;]$ indicates that, along the first axis, positions are to be selected by ω_1 ; along the second axis by ω_2 ; but the last axis (for which no index has been specified) is to be reproduced completely in the result. Similarly:

$\alpha[1\ 2;]$ selects positions 1 and 2 (subject to $\square i o$) from the first axis (rows) and *all* positions from the second axis (columns)

$\alpha[; 1\ 2]$ selects *all* positions along the first axis, and positions 1 and 2 (subject to $\square i o$) along the second axis.

For any axis i for which no ω_i is stated, the shape is $(\rho\alpha)[i]$.

The elements selected from α are those whose positions are described by all possible combinations of the first-axis indexes mentioned in ω_1 with the second-axis indexes mentioned in ω_2 , and so on for all the axes. See Figure 5-29.

Figure 5-29: Expression to select a sub-array from a rank-3 array.

Where an axis is indexed by an item (which has *no* axis), the corresponding axis is *omitted* from the result. For example, when α is a list, $\alpha[2]$ returns an item with no axes because 2 is an item with no axes. See Figure 5-30.

Similarly, when α is a table, $\alpha[1\ 3\ 5;2]$ returns a three-element list, whereas $\alpha[1\ 3\ 5;2]$ returns a 3-by-1 table.

Figure 5-30: Indexing an axis by an item removes that axis from the result.

When any of the selection arrays is present but empty (for example $\alpha[\omega_1;\omega_2]$ when ω_1 is an empty array), the corresponding axis is present in the result, but has length 0.

Indexed Assignment

A bracket expression $\alpha[\omega_1;\omega_2;\dots;\omega_n]$ may appear to the left of the copula. (See the discussion of indexed assignment in Chapter 4, "Naming Nouns and Pronouns".) Such an expression has the form:

$$\alpha[\omega_1;\omega_2;\dots;\omega_n] \leftarrow X$$

Within the brackets, you must have a *valid index expression* or several such expressions separated by semicolons, depending on the rank of α . The requirements for a valid list of indexes are the same as for indexed selection. The expressions inside the brackets imply the shape of a sub-array within α whose elements are to be *respecified*. The indexes for respecification determine the shape of the sub-array in the same way as the indexes of indexed selection, described in the preceding section. This is also the shape of the result received by any other verb to the left of:

$$\alpha[\omega_1;\omega_2;\dots;\omega_n] \leftarrow X$$

The shape of the right argument usually must match the shape implied by the indexes. However, the shape of the right argument ω is acceptable

if it matches the implied length of each axis having a length other than 1. For example, if the implied shape is 2 3, then ω could have shape 2 3, or ω could have shape 1 2 3 or 2 1 3, or 1 2 1 1 3 1, and so on. Similarly, when the implied shape is 2 1 3, the shape of ω would be acceptable if it were 2 3, or 1 2 3, and so on. Those axes of ω whose lengths are not 1 must have the lengths implied by the various index expressions within the brackets.

When ω is an item (or one-item array of any rank), APL reshapes it to match the implied shape.

Effect of Indexed Assignment

APL replaces the indicated positions within α with the values of the corresponding elements of ω .

```
      b←2 3 4⍲24
1  2  3  4
5  6  7  8
9 10 11 12

13 14 15 16
17 18 19 20
21 22 23 24

      b←2 2⍲101 102 103 104
101 102
103 104

      b[1 2;3;1 4]
9 12
21 24

      b[1 2;3;1 4]←b2
101 102
103 104

      b
1  2  3  4
5  6  7  8
101 10 11 102

13 14 15 16
17 18 19 20
103 22 23 104
```

The values inserted must be of the same type (character, numeric, or box) as the array into which they are inserted. For numeric arrays, the inserted values may differ from α in their internal representation (Boolean, integer, floating, or complex). In that case, the entire array α is converted to the internal type required to accommodate the new elements. This affects the space required to store α . For example, inserting an integer other than 1 or 0 into a Boolean array causes the entire array to be converted to integer internal representation, requiring 32 bits per item rather than one bit per item.

In the case where the indexes contain duplicate values, the right-most value is used. For example:

```
v[4]←v[4 4 4]←1 2 3
3
```

Explicit Result of Indexed Assignment

A sentence may make immediate use of the result of an indexed assignment, perhaps like this:

```
x←α[i;]←ω
```

The result of indexed assignment (like the result of assignment generally) is ω , and *not* the merged new value of α . For further discussion, see Chapter 4, "Naming Nouns and Pronouns".

→

6 *Adverbs and Conjunctions*

An adverb modifies the definition of a verb or creates a verb from a noun. A conjunction modifies the definition of a pair of verbs, or a verb and a noun. The modification takes place *before* the verb is executed; what is executed is the modified verb that the adverb or conjunction produces, called the *derived verb*.

Adverb Each of the symbols \wedge , \vee , $/$ and \backslash denotes an *adverb*. An adverb modifies a *single* verb or noun. The adverb symbol follows the symbol for the noun or verb it modifies.

Conjunction Each of the symbols \cdot , \circ , \cup and \cap denotes a *conjunction*. A conjunction *joins* two verbs to form a new derived verb, or joins a noun and a verb. The verbs that each adverb or conjunction can modify are noted in their descriptions, later in this chapter.

An adverb or conjunction can modify a primitive verb. This chapter opens with a summary of general characteristics of adverbs and conjunctions, and then describes each of the primitive adverbs and conjunctions individually.

Precedence of Adverbs and Conjunctions

APL has one rule of precedence:

- *Adverbs and conjunctions are evaluated before verbs.*

All adverbs and conjunctions have equal precedence (just as, among verbs, all verbs have equal precedence). You have to know what derived verb an adverb or conjunction produces before you can parse the rest of the sentence. Therefore, as you read a sentence from left to right, whenever you come to an adverb or conjunction, you evaluate it at once, and replace it and its arguments with the resulting derived verb.

You treat an adverb or conjunction differently from a verb in the following respects:

- When you come to an adverb or a conjunction, *evaluate it at once*.
- When you come to an unmodified verb, *delay evaluation* until you know the value of its *right argument*. (You do not have to delay for the left argument: because you are reading from left to right, you already know what that is.)

Valence of Adverbs and Conjunctions

An adverb is a *monad*. It applies to the noun or verb to its *left*.

A conjunction is a *dyad*. It applies to the verbs (or the noun and verb) *on each side of it*.

Syntactic Class of the Arguments to an Adverb or Conjunction

The effect of an adverb or conjunction depends upon whether its arguments are nouns or verbs – that is, on the *syntactic class* of its arguments. See the section “Syntactic Classes” in Chapter 2, “Grammar”.

- For each *adverb* there are two possible meanings, depending upon whether the argument is a noun or a verb.
- For each *conjunction* there are four possible meanings, depending upon whether each of the arguments is a noun or a verb.¹

For most adverbs and conjunctions there is a *generic name* for the symbol (applicable to all the cases) and specific names for the separate meanings that depend on the valence of the arguments.

Ambivalence of the Derived Verb

Once an adverb or conjunction has produced a derived verb, you can use the derived verb either *dyadically* or *monadically*. The dyad and the monad are sometimes given distinct names, depending on the effects they produce. The various names are noted as part of the description of each adverb and conjunction.

Consecutive Adverbs and Conjunctions

In principle, a sentence may contain a sequence of several adverbs and conjunctions in succession; “A Dictionary of APL” contains numerous examples. The first adverb modifies a verb to produce a derived verb, which in turn is modified by the next adverb, and so on. Currently, an adverb or conjunction in APL can apply only to a primitive verb, not to a derived verb, and therefore cannot occur in a sequence such as $+.\times/$

¹ In APL the noun–noun case does not occur, although it does in “A Dictionary of APL.”

Example to Illustrate Order of Evaluation

Here is an example that mixes some verbs that are *not* modified by adverbs or conjunctions with some that are. Assume that the names A, B, and C refer to nouns. In the diagrams to the right, a dotted enclosure surrounds an area still to be examined, while a solid box encloses a derived verb.

$C \leftarrow A \times^{\circ} 2 - B + 2$

Reading from left to right, the first verb is *subtract*. Since the verb $-$ is not modified by an adverb or a conjunction, it is an ordinary verb. Set it aside until you know what its right argument is.

The next verb is \times , which is modified by $^{\circ}$, the *rank* conjunction. Evaluate the conjunction at once. Its arguments are the verb \times on its left and the number 2 on its right. That gives you the derived verb $\times^{\circ} 2$, read as "times-rank-2." The derived verb $\times^{\circ} 2$ is not modified by another conjunction, but you cannot execute it yet because you do not yet know the value of its argument. Set it aside until its argument is known.

The next verb is $-$. Since it is not modified by an adverb or conjunction, it is an ordinary verb. Set it aside until you know what its right argument is.

The next verb is $+$. It is not modified. You know the value of its right argument. Evaluate it. Replace $B + 2$ with the resulting noun.

Now you know the value of the right argument of the `-` that you set aside two steps ago. Go back and evaluate it. It has no left argument, since to its left there is a verb (the derived verb `x∘2`).

Replace the segment `-noun` with the resulting noun.

Now you know the value of the right argument of the derived verb `x∘2`. Evaluate the derived verb. Replace `Ax∘2-B∘2` with the resulting noun.

Now you know the value of the right argument of the `-` you set aside earlier. Go back and evaluate it. It is the root verb. The sentence has been completely evaluated, and the remaining noun is the result.

Look-Ahead

Reading from left to right requires you to *look ahead*. Each time you come to a noun or verb, you have to check whether it is modified by an adverb or conjunction. You do not have to look far ahead: if there is a modifier, it must be the next thing to the right. Whenever you discover that what is to the right is a noun or verb, that is sufficient to show that your current noun or verb is not modified.

Separating Side-by-Side Constants

Because adverbs and conjunctions have higher precedence than verbs, two nouns may appear side-by-side in a sentence. This happens when both the argument of a conjunction, and the argument of the resulting derived verb are nouns. For example, if you want to find the rank-*n* product of an array *A* and another array *X*, you write:

`A x∘n X`

That sentence is perfectly acceptable. But suppose you know that in a particular case *n* is 1 and that *X* is simply the numbers 4 5 6, and you choose to write those values as constants. The blank, which serves to separate the name *n* from the name *X*, cannot be used to separate the number 1 from the number 4 5 6. If you were to write

```
A *1 4 5 6
```

or even

```
A *1      4 5 6
```

the numbers would run together to form the single noun

```
1 4 5 6
```

Here are some ways to make plain what you intend:²

- | | |
|-------------|---|
| A *1+4 5 6 | Use + to separate the two noun constants. (The verb + returns the argument to the right without changing it. Its presence makes clear that 1 and 4 5 6 are separate nouns.) |
| A *1(4 5 6) | Put parentheses around the derived verb's right argument. |
| A *(1)4 5 6 | Put parentheses around the conjunction's right argument. |

²Although "A Dictionary of APL" allows parentheses around the derived verb, for example *A(*1)4 5 6*, they are not currently permitted in APL.

Adverbs

$v \neq \omega$	v / ω	n / ω	$n \neq \omega$
Reduction, Replicate, Compress			
$v \backslash \omega$	$v \setminus \omega$	$n \backslash \omega$	$n \setminus \omega$
Scan, Expand			

These four adverbs produce a family of derived verbs with the following things in common:

Right rank Each has *unlimited right rank*. That is, it applies to the entire right argument at once, rather than independently to multiple cells within a right-argument frame.

Major cells Each partitions its right argument into *major cells*. The adverb whose symbol has a cross bar (that is, \neq or \backslash) produces a derived verb that splits the argument array into major cells along the *first* axis. That is the standard way.

An adverb whose symbol lacks the cross bar (that is, $/$ or \setminus) produces a derived verb that splits the right argument into cells along its *last* axis rather than the first. They are what this manual sometimes calls *contra-major cells*.⁵

The way in which the derived verb uses the cells in its argument is explained in what follows.

Summary of Forms

The argument of the adverb \neq or \backslash may be either a verb or a noun.

Verb argument The verb's *dyadic* use is understood. Although "A Dictionary of APL" permits any verb, in APL the verb must be a *primitive* and must be a *scalar verb* (that is, a verb whose argument ranks and result rank are all 0). In Figure 6-1, the letter *v* stands for the appropriate verb symbol.

Noun argument The noun must be a numeric list. This list is used to control what is done with the first-axis or last-axis cells into which the derived verb partitions its argument. In Figure 6-1, the letter *n* stands for the appropriate noun.

⁵ Historically, the last-axis split was introduced first, which is why it has the simpler symbols. Recent theoretical work now considers the first-axis definitions to be primary forms and derives the last-axis forms by use of the rank conjunction.

The four forms, with their derived verbs named, and the argument rank of the derived verb that each produces, are summarized in Figure 6-1. (The rank for dyadic use of the derived verb is shown in brackets, since there are no dyadic uses in APL.)

Form $v=$ Verb $n=$ Noun	Name of the derived verb	Rank of the derived verb
$v \rho \omega$	v -reduce ω	oo * *
$v \backslash \omega$	v -scan ω	oo * *
$n \rho \omega$	n -replicates ω n -compress ω (when n is Boolean)	oo * *
$n \backslash \omega$	n -expand ω	oo * *

Figure 6-1: Verbs derived from the slash adverbs.

For the corresponding forms with $/$ rather than ρ and with \backslash rather than \backslash , use the names shown in the figure qualified by the phrase *last-axis*, as in "last-axis reduce," "last-axis scan," and so on.

Monads Scan and Reduce

When the argument of ρ or \backslash is a verb, as in

$v \rho X$ or $v \backslash X$

the derived verb splits the array X into cells and applies the verb v as a dyad between each of them.

Reduce The result of reduction is found by evaluating the verb v between *all* the cells thus formed.

Scan The result of a scan is built up as a series of cells by evaluating the verb v for the first argument cell, the first two argument cells, the first three argument cells, and so on.

Effect of Order of Grouping on Scan and Reduce

Because a scan's n^{th} result cell is constructed from the *first* n cells of the argument, but APL's leaf-to-root execution implies evaluating the *last* verb first, the value of the $(n+1)^{\text{th}}$ cell is obtainable directly from the n^{th} cell only when the verb is associative. You can see this in a simple example with the non-associative verb *subtract*.

Example: Suppose X is a numeric array having three axes, with lengths 4 5 6. A scan or reduce splits X along the first axis, forming four cells, each of which is a 5-by-6 table. Call those tables X_1 , X_2 , X_3 , and X_4 . Then $\rightarrow X$ returns a 4-by-5-by-6 result, whose four tables (each 5-by-6) are computed respectively by:

$$\begin{array}{lll} X_1 & \Leftrightarrow & X_1 \\ X_1 - X_2 & \Leftrightarrow & X_1 - X_2 \\ X_1 - X_2 - X_3 & \Leftrightarrow & X_1 - (X_2 - X_3) \\ X_1 - X_2 - X_3 - X_4 & \Leftrightarrow & X_1 - (X_2 - (X_3 - X_4)) \end{array}$$

The left-to-right grouping for the cells produced by a scan was deliberately adopted because, in this order, the scans produced by several non-associative verbs produce valuable results. For instance:

$\rightarrow \omega$ Alternating sum of cells of ω .

$\leftrightarrow \omega$ Alternating product of cells of ω .

In the result of any scan, the first cell is the same as the first cell in the argument, and the last cell is the same as the result of *reduce*. Thus, the single cell returned by $\rightarrow \omega$ is the same as the last of the cells returned by $\rightarrow \omega$.

Where scans and reductions are defined only for scalar verbs (as is at present true in APL), the result of a scan applied to an array ω has the same rank and shape as the argument ω . The result of a reduction has a rank *one less* than the rank of ω . Indeed, that is why it is called "reduction": it reduces the rank of its argument. (When the argument of reduce already has rank 0, the result also has rank 0.)

Reduce When Argument Has One Cell or None

Since the verb identified in the argument of \rightarrow is interpreted in its *dyadic* sense, you might wonder how the verb is executed when the array argument has only one cell. (What is the sound of one hand clapping?)⁴

By definition, when the array argument of the derived verb has only one cell, the result of reduction by *any* verb is that cell, unchanged. (That holds true even when the values in the argument cell would otherwise be outside the verb's domain, as for example $\wedge \wedge 'a'$.)

When the array argument of the derived verb has *no cells* and the reduction is by a *primitive* verb with a known *identity element*, then the result is a cell whose value is that identity element. An identity element for a dyadic verb

⁴ See also the discussion of identity elements for reduction in the first part of Chapter 5, "Verbs".

is a value that causes the verb to return a result that is the other argument unchanged. Thus, the identity element for addition is 0 because adding 0 to another number does not change it; the identity element for multiplication is 1, and so on.

For *f* (maximum), the identity is that value compared to which all other numbers are greater. In principle, it is minus infinity; in practice, it is the smallest representable number. Similarly, for *l* (minimum), the identity is that value compared to which all other numbers are smaller. In principle, it is infinity; in practice, it is the largest representable number.

For some verbs, there is a right identity but not a left. For example, anything divided by 1 remains unchanged, but the that is not true for 1 divided by anything. For some verbs, there is an identity element when the verb's domain is restricted. For example, as long as you stick to Boolean values, 1 is an identity element for *=*.

When reduction is applied to an empty array, APL returns whatever identity element is defined for the verb. The values of the identity elements are shown in Figure 6-2.

Dyad	Identity Element	Dyad	Identity Element
+	0	∘	None
-	0		0
×	1	!	1
÷	1	○	None
=	1	^	1
≠	0	∨	0
<	0	★	None
>	0	⋄	None
≥	1	⌈	Smallest representable number -7.2370055773322621e75
≤	1	⌊	Largest representable number 7.2370055773322621e75
≡	1		

Figure 6-2: Identity elements for scalar dyads.

Some Examples of Reduce

Reductions and scans are among the simplest, yet most powerful, facilities in APL. The average grade of each student in a course can be found from *S*, their table of quiz scores, by:

$(+/S)+^{-1}PS$

The largest and smallest items in each row of an array are found with \lceil/w and \lfloor/w , respectively.

Questions relating to Boolean criteria are easily answered with reductions on Booleans:

$v/bal>1000$ * Does anyone have a balance in excess of \$1000?

$\wedge/parts\leq catalog$ * Do we have all the parts required?

$+/graph$ * How many paths exist in the graph?

Some Examples of Scan

Scans, like reductions, are effective tools for a variety of computations:

One way to left-justify a table of text is to count the number of leading blanks in each row, then left-rotate each row of the table by that amount. To do this, use *and scan* to locate the leading blanks, and *plus reduce* to sum them:

```

      t←4 9p'This text is not      yet      aligned'
This text
is not
yet
aligned
      t←' '
0 0 0 0 1 0 0 0 0
1 0 0 1 0 0 0 1 1
1 1 1 1 0 0 0 1 1
1 1 0 0 0 0 0 0 0
      A\ t←' '
0 0 0 0 0 0 0 0 0
1 0 0 0 0 0 0 0 0
1 1 1 1 0 0 0 0 0
1 1 0 0 0 0 0 0 0
      +/A\ t←' '
0 1 4 2
      (+/A\ t←' ')÷t
This text
is not
yet
aligned

```

Sum scan can be used to create a moving average function, such as might be used to filter out high-frequency noise, such day-to-day price fluctuations in a series of stocks. Consider a three-day moving average of *prices*, and the sum scan of *prices*:

```

      prices
8 3 1 8 4 7 8
      t←S←+\prices
8 11 12 20 24 31 39

```

If the first two elements of *S* are ignored (three days, remember?), the third item of the sum scan corresponds to the sum for the first three days. The fourth item is the sum of the first four items, the fifth is the sum of the first five, and so on. To get the moving sum, all we have to do is to subtract appropriate numbers from *S*:

- 0 The sum of the first zero elements of *prices* from the third item.
- 8 The sum of the first one element of *prices* from the fourth item.

- 11 The sum of the first two elements of *prices* from the fifth item.
- 12 The sum of the first three elements of *prices* from the sixth item.
- 20 And so on.

Noting that these numbers, aside from the first zero, are merely elements of the sum scan, we can complete the moving sum with the following expression:

```
(2+S)-0,~3+S  
12 12 13 19 19
```

The complete expression for the α -period moving average of a list ω is:

$$(((\alpha-1)+r)-0,(-\alpha)+r+\backslash\omega)+\alpha$$

The addition of two rank conjunctions allows the verb to be used on arrays of higher rank:

$$(((\alpha-1)+\overset{\circ}{\vee}1\ r)-0,(-\alpha)+\overset{\circ}{\vee}1\ r+\backslash\omega)+\alpha$$

Scans on Boolean arguments are also powerful. $\neq\backslash$ computes the running parity of a Boolean list. This can be used for such purposes as locating quotes in text. $<\backslash$ will isolate the first 1 in each row of a Boolean array.

The Derived Verbs Replicate and Expand

When the argument of \neq or $\neq\backslash$ is a noun, the derived verb splits its argument into cells and then *copies* (or *replicates*) the argument cells, or expands the argument array by inserting new cells.

- | | |
|--|---|
| $n \neq \omega$ or n / ω | Makes n copies of the cells of ω . |
| \neq | copies major (first-axis) cells. |
| $/$ | copies contra-major (last-axis) cells. |
| $n \neq\backslash \omega$ or $n \backslash \omega$ | Inserts "fill" cells between existing cells of ω . |
| $\neq\backslash$ | inserts major (first-axis) cells. |
| \backslash | inserts contra-major (last-axis) cells. |

Replicate

The adverb's argument n indicates the number of times to copy each major cell of the derived verb's argument. Each item in n must be a non-negative integer, and the length of n must match the length of the appropriate axis

of ω . Alternatively, where n is an item, it is applied to each of the cells in ω .

The number of cells in the result is the sum of the values in n (or n times the number of cells, when n is an item). The result consists of *replications* of the cells of the right argument. For example:

```

      1-X ← 3 7 'First' 2 'Second' 3 'Third'
First
Second
Third

      3 0 2 7 X
First
First
First
Third
Third

      2 0 4 7 1 3 1 1 0 1
1 1 3 3 3 3

      3 7 'abc'
aaabbbcccc

```

Compress

A commonly used subset of replicate occurs when the values in the list n are Boolean (that is, are all either 0 or 1). In such a case, a cell from the derived verb's argument is either retained in the result (where n has a 1) or discarded (where n has a 0). In that case, the derived verb is called *compress*, since the result differs from the argument only in having certain cells removed. This often occurs in an expression in the form:

(*Proposition on ω*) 7 ω

Here *Proposition on* stands for any APL expression that takes ω as an argument and returns a Boolean result with a 0 or 1 for each major cell in ω ; for example, $(0 \in \omega) \neg 1 \omega$ ("accept any cell that contains a zero"). The result of this compression retains from ω those major cells for which the proposition is true (represented by 1) and omits those for which the proposition is false (represented by 0).

For example, the set of odd numbers could be extracted from a list of numbers using compress in this way:

```
      L
1 9 2 22 55 987 88 100 .5 33333
      (1=2|L)/L
1 9 55 987 33333
```

Expand: Introducing "Fill" Cells

The noun argument to \times or \backslash is required to be a *Boolean list* in which the number of occurrences of a 1 agrees with the number of cells along the axis of the array you are about to expand. Occurrences of a 0 produce *fill items* appropriate to the type of the array you are expanding:⁵

```
0      for a numeric array
' '    for a character array
<10   for a boxed array.
```

For example, using the array *X* defined above to illustrate *replicate*:

```
      '*', 1 0 1 0 1  $\times$  X
*First
#
*Second
*
*Third
```

Derived Verbs Modified by Axis Bracket Notation

All the derived verbs produced by \neq / \times or \backslash work by *partitioning* the derived verb's right argument into cells. As mentioned, the derived verbs produced by \neq and \times partition along the first axis, while those produced by / and \backslash partition along the last axis. You can override the axis along which partitioning takes place by modifying the derived verb with the *axis adverb*.⁶ For example, the expressions

$\neq\{1\} \omega$	$\neq\{1\} \omega$
$\neq/[1] \omega$	$\neq/[1] \omega$
$\neq\{1\} \omega$	$\neq\{1\} \omega$
$\neq\backslash[1] \omega$	$\neq\backslash[1] \omega$

⁵ Fill items are described in detail in Chapter 5, "Verbs" in the sections on "fill elements" and "over-take and padding."

⁶ Although axis bracket notation does not adhere to the syntax or semantics of adverbs, its behavior is closest to that of an adverb, hence its appearance here. "A Dictionary of APL" treats the use of brackets to indicate an axis as a holdover from early APL implementations and mentions it only as a "dialectical variant." However, it is included in the 1984 ISO standard for APL and is retained in APL.

all mean that the derived verb partitions the array ω along its i^{th} axis rather than along the first or last. The value of i used by the bracket axis adverb is sensitive to the value of $\Omega i \alpha$.

Conjunctions . ⍷ ⍶ ⍵

For every conjunction, four cases are possible, based on the name-class of the arguments:

- both verbs
- a noun and a verb
- a verb and a noun
- both nouns.

At least in theory, each of these cases may produce an ambivalent derived verb (which may be used either monadically or dyadically). In practice, some of the cases are not implemented or defined. Figure 6-3 summarizes the available cases.

Argument	Valence	⍷	⍶	⍵	.
Verb, verb	Monadic	UPON	ON	UNDER	ALTERNANT
	Dyadic	UPON	ON	UNDER	PRODUCT
Noun, verb	Monadic		CUT		
	Dyadic		CUT		
Verb, noun	Monadic		RANK		
	Dyadic		RANK		

Figure 6-3: Conjunctions.

Grouping in the Discussion of Conjunctions

In the sections that follow, the discussion of conjunctions is grouped not by symbol but by related use. The sections are:

Composition: ⍷ ⍶ ⍵ with arguments ν ν

Rank: ⍶ with arguments ν $\#$

Cut: ⍶ with arguments $\#$ ν

Product: . with arguments ν ν

Conjunctions \circ $\circ\circ$ $\circ\circ\circ$ with Verb Arguments

When one of the conjunctions \circ , $\circ\circ$, or $\circ\circ\circ$ is used between a pair of verbs, it forms a new verb that is a sort of *composition* of the two verbs. In what follows:

f denotes the verb that is the conjunction's left argument

g denotes the verb that is the conjunction's right argument.

Each of the three conjunctions \circ , $\circ\circ$, and $\circ\circ\circ$ may take two verbs as its arguments: one verb which it uses *monadically*, and another which it uses *ambivalently*. Each of the three conjunctions produces an *ambivalent* derived verb. They differ in which of the argument verbs is monadic and which ambivalent, as follows:

$f\circ g$ *Upon*. The right argument g is the ambivalent one. It acts on corresponding cells of the derived verb's array arguments α and ω (or just on cells of ω when α does not exist).

$f\circ\circ g$ *On*. The left argument f is the ambivalent one. It acts on the corresponding cells produced by applying g to cells of α and to cells of ω (or just to cells of ω when α does not exist).

$f\circ\circ\circ g$ *Under*. Like $f\circ\circ g$. However, to each of the cells produced as in $f\circ\circ g$, it then applies g' , the inverse of g .

Under Requires a Known Inverse

Because $f\circ\circ\circ g$ automatically applies not only the monadic verb g but also its inverse, the choice of g in compositions such as $f\circ\circ\circ g$ is limited to verbs for which APL already knows the inverse. Therefore, g must be taken from the following list of primitive monads (inverses shown below).

Monad: \star \bullet $>$ $<$ $-$ $+$ \square \blacksquare \sim \vdash $+$

Inverse: \bullet \star $<$ $>$ $-$ $+$ \square \blacksquare \sim \vdash $+$

Several of these verbs are self-inverse. The verb \vdash is self-inverse because, used monadically, it is an identity function (giving back as result the same value it received as argument).

Derived Verbs Produced by Composition

In Figure 6-4:

LA denotes the left array argument of the derived verb

α denotes a cell within LA

RA denotes the right array argument of the derived verb

ω denotes a cell within RA .

Name	APL expression	Valence required	Effect
Upon	$f\bar{O}g\ RA$	$f: 1\ g: 1$	$f\ g\ \omega$
	$LA\ f\bar{O}g\ RA$	$f: 1\ g: 2$	$f\ \alpha\ g\ \omega$
On	$f''g\ RA$	$f: 1\ g: 1$	$f\ g\ \omega$
	$LA\ f''g\ RA$	$f: 1\ g: 2$	$(g\ \alpha)\ f\ g\ \omega$
Under	$f'''g\ RA$	$f: 1\ g: 1$	$g'\ f\ g\ \omega$
	$LA\ f'''g\ RA$	$f: 1\ g: 2$	$g'\ (g\ \alpha)\ f\ g\ \omega$

Figure 6-4. Composition templates.

Default Rank of the Derived Verb

A conjunction can accept as a right argument only a primitive verb having a known default argument rank. Thus, a verb whose default argument rank is shown by a $*$ (in Figure 6-1 or in the descriptions of the various verbs in Chapter 5, "Verbs") is ineligible.

In all cases, the compositions are considered *close*; that is, they are applied *independently to each cell* of their array argument (when they are used monadically) or to each of the *pairs of corresponding cells* (when they are used dyadically).

The verb derived from a composition conjunction divides its argument(s) into cells in the same way as would g , the verb to the conjunction's *right*. In particular, the rank of a verb derived from $f\bar{O}g$ is the same as the rank of g , and the rank of verbs derived from either $f''g$ or $f'''g$ is the same as the *monadic rank* of g .

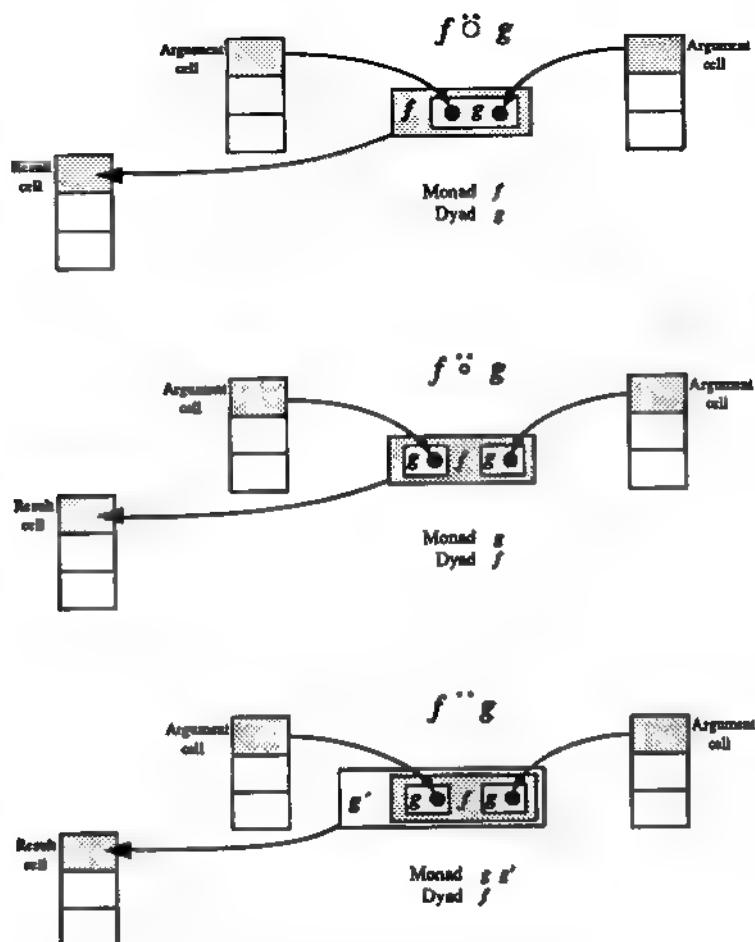

Figure 6-5: Three forms of composition.

The diagram in Figure 6-5 presents a graphic summary of the way the argument verbs of the three conjunctions are applied to cells of the argument array when the derived verb is used dyadically.

The Rank Conjunction $\overset{\circ}{\circ}n$

When the left argument of $\overset{\circ}{\circ}$ is a verb and the right argument is a noun, the noun specifies the verb's *argument rank*. For example, the expression

$$\alpha + \overset{\circ}{\circ}0 \ 2 \ \omega$$

indicates that the verb $+$ is to be applied to rank-0 cells of α and rank-2 cells of ω . That is, each item in α is to be added to the corresponding table in ω . (The frame-shapes have to match. That is, the arrangement of items in α has to match the arrangement of tables in ω .)

Similarly, the expression

$$<\overset{\circ}{\circ}1 \ \omega$$

encloses each list (that is, each rank-1 cell) of ω .

The noun argument of $\overset{\circ}{\circ}$ must be an item or a list, and it may have one, two or three integers. It takes three items to describe the verb's monadic rank and the dyadic ranks of its left and right arguments. When the argument n has fewer than three items, the values for all three are implied by the expression

$$\phi 3 \rho \phi n$$

Calling the items within the noun a , b , and c respectively (when the noun has one, two, or three items), they specify the argument ranks as shown in Figure 6-6.

n	Monadic rank	Dyadic left rank	Dyadic right rank
$a \ b \ c$	a	b	c
$a \ b$	b	a	b
a	a	a	a

Figure 6-6: Short forms of rank specification in $\overset{\circ}{\circ}$.

Argument Rank vs. Complementary Rank

When an item in the right argument of ω is positive, it specifies the number of *trailing* axes in an argument cell. Any remaining axes are frame axes.

When an item in the right argument of ω is negative, its magnitude specifies the number of *leading* axes in the argument frame. Any remaining axes are cell axes. It is thus the complement of the way rank is specified by a non-negative right argument.

For each of the cells within the frame thus defined, the verb is evaluated with its "ordinary rank": as it would be evaluated if not modified by the rank conjunction. For example,

$\omega \leftarrow 1 \omega$

specifies that the frame rank is 1, and thus ω is applied independently to each of the major cells of ω .

Within Cells, the "Ordinary" Rank Applies

The rank conjunction controls the initial partitioning of the arguments into frame and cells. To each of those cells, the verb's "ordinary" definition applies – the definition unmodified by the rank conjunction.

When the cells thus defined have a rank greater than the rank for which the verb is defined, then the verb is applied to each cell with its *default rank* – provided default rank is defined for that verb. For example, to add the nine-element list α to each of the rows of the nine-column table ω , you write:

$\alpha + \omega$

That pairs the list α with the list $\omega[1;]$, then with the list $\omega[2;]$, and so on. For the first result cell, the interpreter evaluates:

$\alpha + \omega[1;]$

The verb $+$ had default argument-rank 0. The verb $+$ is then applied to the arguments α and $\omega[1;]$ with rank 0. That causes a new level of partitioning between frame and cell. In this example, each argument cell is partitioned into a nine-element frame consisting of rank-0 cells. $\alpha[1]$ is added to $(\omega[1;])[1]$, $\alpha[2]$ is added to $(\omega[1;])[2]$, and so on.

Default Rank Not Defined for Some Verbs

A verb's *default rank* is the argument rank it assumes when the rank is not explicitly stated with the rank conjunction. For example, monadic use

of `⌿` has default rank 2. If `x` is a rank-3 array and you write `⌿x`, it is automatically assumed that you mean to apply `⌿` to each 2-cell of `x`.

For some verbs, no default rank has yet been defined. For example, `monad` `⌈` is defined when `ω` is an item (or a one-item list). If `x` is a rank-3 array and you write `⌈x`, it is *not* assumed that `x` is to be treated as a collection of rank-0 cells and `⌈` evaluated for each. Instead, the expression is rejected as a rank error.

When you use a verb for which default rank has not been defined, the rank conjunction can be used only to assign a rank acceptable in the ordinary case. For example, the expression `⌈∘0 x` is valid because `⌈` works on a rank-0 argument. And the expression `⌈∘1 x` works when the last axis of `x` has length 1 (because `⌈` works on a one-item list, even though it cannot handle a list of any other length).

That is the point of the phrase "ordinary rank" in the preceding section. When you use the rank conjunction to partition the argument into cells, the interpreter applies to each cell the ordinary definition of the verb. When the verb has a default rank, the default rank is used; this may then lead to a further partitioning within each argument cell. But where there is no default rank, the "ordinary rank" – the rank with which the verb is ordinarily used – is the only one permissible. In these cases, you have to supply arguments that meet the verb's requirements for rank and shape.

Examples of Rank

Before the rank conjunction was available, adding a list to each row of a table might have performed with an expression such as:

```
table+(⍶table)⍶list
```

With rank, it is you merely specify the use of rank-1 cells:

```
list+∘1 table
```

The use of rank allows terser expression as well as offering the potential for faster execution in less space. Adding a list to each column of a table is a bit subtler, but is done as follows:

```
list+∘0 1 table
```

This takes advantage of scalar extension in `+`, by setting up scalar cells from the list, and list cells from the table. Effectively, each element of the list is added to the corresponding row of the table.

The Cut Conjunction $n \circ \circ v$

When the left argument of $\circ \circ$ is a noun (other than 0) and the right argument is a verb, the derived verb *cuts* the argument array ω into segments by splitting it at points along its first axis. A 0-cut selects arbitrary cells from the argument array. Cut then applies the verb on the right to each of the segments thus obtained.

The left argument n of $\circ \circ$ is an integer specifying the *type of cut*. n must be an item; frame considerations do *not* apply to it. The value of n must be one of -2, -1, 0, 1 or 2.

When the derived verb is used dyadically, the derived verb's left argument α specifies the *positions* in ω at which ω is to be cut. To each of the cells produced by a cut, the verb v is applied *monadically*.

Between them, the derived verb and the conjunction have four arguments; they are summarized in Figure 6-7.

α	n	$\circ \circ$	v	ω
<i>Where to cut</i>	<i>Type of cut</i>		<i>Verb (monad)</i>	<i>Array argument of the derived verb</i>
Offset and length (required)	0			(to be cut based on the value of the left argument)
Boolean mask (optional)	non-0			

Figure 6-7: Arguments of the cut conjunction and of its derived verb.

Types of Cuts

For every type of cut, the derived verb has unlimited right argument rank: it applies to the whole array, not independently to cells within the array. When the derived verb is used dyadically, its left argument rank is either 1 or 2, depending on the type of cut.

The type of cut is controlled by the value of n as follows:

- $n=0$ Each cell is selected by an *integer table* specifying the *offset and length* along each axis
- $n \neq 0$ Cells are selected by a *Boolean list* delimiting segments along the *first axis* of ω .

Cells Selected by Table

When n is 0, the derived verb has left argument rank 2. Each *table* in α describes the *position and shape* of a cell passed to the verb v . The description is a table having two rows and a column for each axis of ω .

Within each α -cell, rows have significance as follows:

Row 1: *Offset* along ω 's various axes after which a block is to start. For example, an offset of 2 means that you skip the first two positions before starting the block. A negative offset means "all but." For example, an offset of -2 means you skip all but the last two positions before starting a block. An offset of 0 starts at the beginning of an axis; an offset equal to the length of the axis means "start at the end"; it is valid only when the length you ask for is 0. The magnitude of the offset may not exceed the length of the corresponding axis of ω .

Row 2: *Length* along each axis for the block you are selecting. The magnitude of the value you write here governs the length of the block. The offset plus the magnitude must indicate positions that actually exist along the corresponding axis of ω .

The sign of a value in row 2 affects neither the size of the block you select nor the positions from ω that go into it. The sign controls the *order* in which the selected positions appear in the block. A negative value selects the same positions, but places them in the segment that is passed to the verb v in reverse order.

For example, here is an α -cell that describes a segment to be cut from a rank-3 array ω . Since ω has three axes, an α -cell must have three columns. Thus,

```
4  -3  5
2   1 -3
```

indicates that from the right argument a cell is to be extracted as follows:

Axis 1: *Offset:* Start four positions after the beginning of this axis.

Length: From there, continue for two positions;

Axis 2: *Offset:* Skip all but the last three positions of this axis.

Length: From there, run for one position in the standard direction (that is, towards the end of the axis).

Axis 3: *Offset:* Start five positions after the beginning of this axis.

Length: From there, run for three positions in the usual direction (that is, towards the end of the axis). However, because the length is negative, place the selected positions in reverse order in the cell passed to verb v .

The 0-cut requires a considerably more elaborate left argument than the 1-cut or 2-cut, with a distinct α -cell for each cell passed to v . However, the 0-cut permits you to specify the lengths a segment has on *all* its axes, not just the first. It also permits *overlapping* segments, or *empty* segments.

The following example shows how multiple pieces may be selected in parallel from a table:

```

t←5 5p125
1 2 3 4 5
6 7 8 9 10
11 12 13 14 15
16 17 18 19 20
21 22 23 24 25

t←4 2 2p0 0 2 3,0 0 ^2 ^3,1 2 3 2,2 ^2 ^3 1
0 0
2 3

0 0
^2 ^3

1 2
3 2

2 ^2
^3 1

c 0%t
┌───┬───┬───┬───┐

├───┼───┼───┼───┤
│   │   │18 19│14│
├───┼───┼───┼───┤

```

Cells Selected by Boolean Partition

When ω is other than 0, the derived verb has a left argument of rank 1. Each item 1 in the α -cell marks the start (or end) of a cell passed to the verb v . Each Boolean list therefore generates as many cells as it contains 1s. To permit the result to be constructed, each α -cell must contain the same number of 1s. The box verb (\llcorner) is often used to make this possible.

Each cell has the same rank as ω and the same length as ω along all its axes except the first. Along the first axis, a cell passed to v has a length

that depends on the distance between consecutive 1s in the α -cell. The positions selected for each cell are controlled by the value of n as follows:

- $n \leq 1$ Each 1 in an α -cell marks the start of a segment. The first segment starts at the first 1; positions before it are *not* represented in the result.
- $n \leq -2$ Each 1 in an α -cell marks the end of a segment. The last segment ends at the last 1; positions after it are *not* represented in the result.
- n positive The position corresponding to each 1 in an α -cell is included in the result cell.
- n negative The position corresponding to each 1 in an α -cell is not included in the result cell.

To make the selections produced by cut readily visible, use $<$ as the right argument, putting each cell into a box, and make the boundaries of the boxes explicit in the display by setting by setting Ωps to $\bar{1} \bar{1} \bar{3} \bar{3}$. Then $\alpha \bar{n} < \omega$ shows how the n -cut divides the array argument. For example:

```

w←' Worlds on worlds'
(w←' ') 1∘w ← Ωps←-1 1 3 3
┌────────┐┌──┐┌────────┐
│ Worlds │ │ on │ │ worlds │
└────────┘└──┘└────────┘

(w←'Now') -1∘w
┌──┐┌────────┐┌──┐┌──┐┌────────┐
│w │ │ orlds │ │ on │ │ w │ │ orlds │
└──┘└────────┘└──┘└──┘└────────┘

```

APL programmers make extensive use of Booleans, particularly in the partitioning of data. One way to easily find the lengths of the partitions in a Boolean partition vector is to let cut do the work for you:

```

1∘p1 0 0 0 1 1 0 0 1 0
4
1
3
2

⍝Table⍝ 5 4p120
1 2 3 4
5 6 7 8
9 10 11 12
13 14 15 16
17 18 19 20

```

```

      (1 0 0 1 0) ^1⍷< Table ← Qps←1 1 3 3
┌──────────┬──────────┐
│5  6  7  8│17 18 19 20│
├──────────┼──────────┤
│9 10 11 12│          │
└──────────┘

```

Monadic Use of 1- and 2-Cuts

The 1-cut and 2-cut, but not the 0-cut, can be used monadically. When you use the derived verb monadically, the cuts are made by treating the first (or last) of the major cells of ω as the delimiter. The result is what you would get if you had included α as the Boolean list computed as:

$$\alpha \leftarrow \omega \equiv \bar{\omega}^{-1} \vdash >, < \bar{\omega}^{-2} (1 + \omega) \quad \text{when } 1 = |\alpha|$$

or

$$\alpha \leftarrow \omega \equiv \bar{\omega}^{-1} \vdash >, < \bar{\omega}^{-2} (\bar{1} + \omega) \quad \text{when } 2 = |\alpha|$$

That is, the partition list α is formed by comparing the major cells of ω with the first major cell or the last major cell of ω .

For example, the following encloses each word (delimited by a blank) in the character string ω

$$\bar{1}\bar{\omega} < \text{ ' ' }, \omega$$

while the following arranges each of the equal length character strings between slashes into a table

$$\bar{1}\bar{\omega} \vdash \text{ ' ' }, \omega$$

Shape of the Result Produced by Cut

The result produced by dyadic use of a verb derived from cut has the frame-shape required by the values in α , followed (when $n \neq 0$) by the number of partitions, followed by the common cell-shape resulting when the verb v is applied to the cut cells. Because APL currently requires that result cells agree in rank and shape, the *box* adverb is often used to force all result cells to be items.

Dot Conjunctions

The following table summarizes the cases of the dot conjunction, and the names associated with them. *Outer product*, *Inner product* and *Alternant* are discussed separately in what follows.

Argument	Monadic use of the derived verb	Dyadic use of the derived verb
$\alpha \quad v$		Outer Product
$v \quad \omega$		
$v \quad v$	Alternant (Determinant)	Inner Product

Figure 6-8: Verbs derived from the dot conjunction.

Tie and Outer Product

The APL *outer product* is a particular case of what "A Dictionary of APL" calls *tie*.⁷ The outer product relaxes the usual rules regarding agreement of frames, and instead pairs each 0-cell of α in turn with each of the 0-cells of ω . The result contains all possible pairings of an α -cell with an ω -cell. The resulting frame has shape $(\rho\alpha), (\rho\omega)$.

The outer product is written:

$$\alpha \cdot g \omega$$

The argument g must be a primitive scalar verb (that is, one that is defined for rank-0 arguments and that returns a rank-0 result).

The result is obtained by pairing each element of α with each element of ω . One might specify the result r by the following formula:

$$\begin{aligned} \text{shape } r &= (\rho\alpha), \rho\omega \\ r &= ((\rho\omega)\rho\alpha 1 \ 0 \ \alpha) \ g \ \text{shape}\rho\omega \end{aligned}$$

Notice that when either α or ω is an item, an outer product gives the same result as the verb without the dot conjunction.

When the arguments are lists, the result is a table. For example, if α is the first three integers and ω the first five, then $\alpha \cdot \times \omega$ forms a multiplication table:

⁷ In "A Dictionary of APL," the $\alpha \cdot v$ case of the dot conjunction relaxes the agreement rules for the frames of a dyad. Whereas ordinarily α and ω must have the same frame-shape (and the verb is evaluated for each pairing of an α -cell with the corresponding ω -cell), the *tie* conjunction allows you to specify how many axes must agree. This leaves all the other (leading) axes free. The α agreeing axes are said to be *tied*. The result's frame-shape is then the (untied) frame-shape of α followed by the (untied) frame-shape of ω . When the number of tied axes is 0, you have the outer product. As a substitute for $\alpha \cdot g \omega$, "A Dictionary of APL" permits $\alpha \cdot g \omega$, which is the form provided in APL.

```

      α × ω ← α←1 2 3 4 ω←1 2 3 4 5
1  2  3  4  5
2  4  6  8 10
3  6  9 12 15

```

Below appears a division table formed from the same lists α and ω :

```

      α ÷ ω
1      0.5      0.3333333333 0.25      0.2
2      1        0.6666666667 0.5       0.4
3      1.5      1          0.75      0.6

```

The expression $\alpha \geq \omega$ produces a logical map showing where an element of α is not less than an element of ω :

```

      α ≥ ω
1 0 0 0 0
1 1 0 0 0
1 1 1 0 0

```

Other Boolean verbs also produce interesting results:

```

      α = ω
1 0 0 0 0
0 1 0 0 0
0 0 1 0 0

```

```

      α < ω
0 1 1 1 1
0 0 1 1 1
0 0 0 1 1

```

Similarly, $\alpha \mid \omega$ produces a table of residues or remainders:

```

      α | ω
0 0 0 0 0
1 0 1 0 1
1 2 0 1 2

```

And $\alpha - \omega$ gives a table of the differences between elements of α and those of ω :

```

      α - ω
0 -1 -2 -3 -4
1  0 -1 -2 -3
2  1  0 -1 -2

```

If *alf* is a list containing the letters of the alphabet, and *text* is a list representing the text of a document, then *alf*.text* gives you an incidence map showing where the letters of the alphabet are in the text, while *+/alf*.text* gives you the number of occurrences in *text* of each letter in *alf*.

Inner Product

The expression *α+.ω* is equivalent to the *dot*, *inner*, or *matrix* product as defined in mathematics for vectors (*+/α×ω*) and matrices (where the element in row *i* and column *j* of *α+.ω* is the dot product of row *i* of *α* and column *j* of *ω*). For example:

```

1 2 3 +.× 3 4 5
26

a←2 3ρ16 ← b←3 4ρ12 ← ⍺10+1
a +.× b
38 44 50 56
83 98 113 128

a +.× 1 2 3
14 32
```

The inner product can be used not just with *+* and *×* (the dot product of matrix algebra) but with any of the primitive verbs that take item arguments and return item results. For example:

```

a 1.+ b
2 3 4 5
5 6 7 8

a +.1. b
6 6 6 6
12 13 14 15
```

Result Shape of Inner Product

The result produced by an inner product resembles the shape produced by outer product, except that the two inner axes — the last axis of *α* and the first axis of *ω* in *α f.g ω* — disappear in the result. Hence, the shape of the result of *α f.g ω* is $(-1+ρ_α), 1+ρ_ω$.

Extending One Argument to Match the Other's Length

In general, the inner axes (that is, the last axis of *α* and the first axis of *ω*) must match in length. However, APL also accepts two other cases:

- When the inner axis of one argument has length 1, but the inner axis of the other argument has some other length, APL treats the length-1 axis as though it were extended to match the length of the other one, replicating in each position whatever value is in the first position.
- Similarly, when one argument is an item, APL treats it as if it were a list of the same length as the inner axis of the other argument, replicating at each element the value of the item.

Neither of these extensions affects the shape of the result.

Inner Product and Matrix Product

When α and ω are matrices, the inner product $\alpha+.x\omega$ is the same as the ordinary matrix product of matrix algebra. Note that matrix product has an inverse, since, where α and ω are non-singular square matrices:

$$\omega \iff (\alpha+.x\omega)\alpha$$

See the discussion of matrix division and matrix inverse in the discussion of \div in Chapter 5, "Verbs".

Evaluation of polynomials. The ordinary matrix product $\alpha+.x\omega$ can evaluate polynomials in ω . Suppose *coeff* is a table (of any rank or shape) containing the coefficients of the polynomials to be evaluated. The first axis of *coeff* contains the terms, starting with the constant term, the first degree, second degree, and so on, up to the desired degree. Let *powers* be an array in which each member of α is raised to each of the powers, from zero up to whatever degree is implied by the length of the first axis of *coeff*. That can be calculated by:

$$\text{powers} \leftarrow \alpha \times. \times (\text{1} + \rho \text{coeff}) - \text{1} \text{ 1 0}$$

Then all of the polynomials for each of the sets of coefficients in *coeff* can be calculated by:

$$\text{powers} +. \times \text{coeff}$$

Product of powers. One way to represent an integer is by its prime factorization. That is, you can represent an integer by a list indicating to what power each of its possible prime factors must be raised. The integer is then the product over each of those powers. For all the primes in order out to the largest one needed, suppose *factors* is an array containing the power to which each must be raised. Then the values represented by such a set of prime factors are found by

$$\text{primes} \times. \times \text{factors}$$

where *primes* is a list of the values of as many primes as are needed to match the length of the first axis of *factors*.

Locating characters from one table within another. Inner products constructed from logical verbs on character data are frequently useful in handling textual data. Suppose *sample* is a character matrix in which each row contains characters spelling a word, phrase, or name. Suppose *reference* is a similar table of recognized words or phrases. You need to know where within *reference* each row of *sample* is to be found. A map showing where each row of *sample* is entirely equal to a row of *reference* is obtained by:

```
reference ∧.= ⍵sample
```

Alternatively, rather than identifying those rows of *reference* which are entirely equal, you might wish to eliminate those that are in any way different, by an expression such as:

```
reference ∨.≠ ⍵sample
```

If you want to convert the resulting Boolean map so as to identify the number of the row on which each match was found, that might involve another inner product. Suppose *iota* is a list of consecutive integers, with as many members as there are rows in *reference*, perhaps formed by the expression:

```
iota←1↑⍳reference
```

The location of the match for each row of *sample* is found by:

```
iota +.× reference ∧.= ⍵sample
```

The preceding formula assumes that *reference* does not contain duplicate entries. But if it did, and you wanted the highest entry, you could find it

```
iota ⌈.× reference ∧.= ⍵sample
```

If you are interested in the extent of agreement (rather than simply the Boolean decision whether or not there is perfect agreement), you might get that by:

```
reference +.= ⍵sample
```

Permutation and partition matrices. You can permute or partition the members of one array by making one of the arguments of an inner product a Boolean array. The Boolean matrix *b* might contain a column for each of the desired partitions. In the expression $b +. \omega$, a 1 in *b* indicates that a row of ω is included in a partition, and a 0 indicates that it is not.

When there are as many partitions as there are rows, and each row and column contains exactly one 1, the matrix is a *permutation matrix*. It specifies an order in which the rows of ω are represented in the result of $b +. \omega$.

of the sine is shown conventionally as the alternating sum of ratios of successive odd powers:

$$\sin x \approx x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \frac{x^9}{9!} +$$

In APL, this simplifies to the $-.\div$ inner product, as follows:

$$\sin x \leftarrow (x \circ .\div \text{odd}) -.\div 1 \text{ odd} \div 1 + 2 \times 1 \div k \div 1 \div 1 \div 1 \div 1$$

Monadic Use: The Alternant

The expressions $-\times \omega$ and $+\times \omega$ are, for square matrix arguments ω , the *determinant* and the *permanent* of mathematics.⁵

The generalization to arguments other than $+$, $-$, and \times is based on constructing the determinant as an alternating sum ($-./$) over products over the diagonals of matrices obtained by permuting the major cells of ω .

Applied to a matrix of coefficients of a set of linear equations, the determinant identifies the character of the solutions; applied to the matrix of partial derivatives of a vector function on vector arguments it yields the volume transformation effected by the function; and applied to the matrix $s, 1$ it yields $1! + P s$ times the signed volume of the simplex of $n+1 + P s$ vertices in $(n+1)$ -space.

The determinant is generated by the expression

$$-\times N$$

where N is a rank-2 array, usually square, but possibly with more rows than columns. Only the "top-left square" portion of an array with more columns than rows is considered; that is, N is truncated to be $(I/PN) \uparrow N$.

The general case $f.g N$ is defined analogously as reduction by f over a set of $1n+1 \div P N$ "products" produced by reduction by g over $1n$ distinct sets of n elements chosen one from each row and column of N .

The ordinary determinant $-\times N$ on a square matrix may be used as a test for invertibility before applying \mathbb{I} .

The determinant of a square matrix N may be defined as the alternating sum ($-./$) of the $1n+1 \div P N$ products over n elements chosen (in each of the $1n$ possible ways) one from each row and column. Analogous calculations in which other function pairs are substituted for $-$ and \times lead to other

⁵ The discussion that follows is condensed from "A Dictionary of APL," and from E.H. Iverson, *Determinant-Like Functions Produced by the Dot Operator*, SAIN 42, Toronto: I.P. Sharp Associates, 1962.

useful functions; examples include the pairs $\downarrow, \uparrow M$, $\wedge, \vee M$, and $+, \times M$, the last (called the *permanents*) being useful in combinatorics.⁸

Suppose M is a magic square of order 3, then:

```

      M
6 7 2
1 5 9
8 3 4

      -, ×M
360

      +, ×M
900

      ∨, ∧M
2

```

Non-Square Arguments

The extension of the alternant to non-square arguments allows the use of the determinant $-, \times$ on an $n+1$ -by- n argument to compute the signed volume of the simplex it represents in n -space.

When M has more rows than columns, $\times/s+(1+PM)+\phi(1+PM)$ distinct sets of $1+PM$ elements can be selected without repetition of either column or row, and these are arranged in lexical order in an array of shape s . For example:

```

      M←F4 209
6 4
5 5
4 3
1 4

      -, ×M
21

```

For a wide matrix M , the result of $f.g\ M$ is equivalent to $f.g\ (1\backslash PM)+M$.

The case of $-, \times$ applied to an $n+1$ -by- n matrix is of special interest because it is equivalent to $-, \times M, 1$, and can therefore be used to compute the volume

⁸ See H.J. Ryser, *Combinatorial Mathematics*, *Carus Mathematical Monograph Number 14*, Mathematical Association of America, distributed by John Wiley and Sons, Inc., Providence, R.I., 1963.

of the simplex defined by N without explicit catenation of a final column of 1s.

If a , b , and c are two-element vectors, then

$$-. \times N \leftarrow 3 \ 2Pa, b, c$$

yields twice the signed area of the triangle with vertices a , b , and c . The sign of the result depends on the order of the vertices, positive when they are in counterclockwise order and negative when they are in clockwise order. For example, if:

$$a \leftarrow 1 \ 1 \leftarrow b \leftarrow 1 \ 0 \leftarrow c \leftarrow 0 \ 1$$

$$-. \times 3 \ 2Pa, b, c$$

-1

$$-. \times 3 \ 2Pb, a, c$$

1

The signed result of $-. \times N$ is significant in higher dimensions as well. If a , b , c , and d are points in three-space (in a dextral coordinate system), then

$$-. \times 4 \ 3Pa, b, c, d$$

gives (12) times the signed volume of the tetrahedron, the results being zero if the points are coplanar, and positive if the points b , c , and d are in counterclockwise order when viewed from a . For example:

$$a \leftarrow 1 \ 1 \ 1 \leftarrow b \leftarrow 1 \ 0 \ 0 \leftarrow c \leftarrow 0 \ 1 \ 0 \leftarrow d \leftarrow 0 \ 0 \ 1$$

$$-. \times 4 \ 3Pa, b, c, d$$

2

$$-. \times 4 \ 3Pa, c, b, d$$

-2

The use of functions other than $-$ and \times can be illustrated in the context of the so-called *assignment* problem. One of n persons (or machines) is to be assigned to each one of n tasks in some optimal way, the cost associated with assigning person i to task j being given by element $M[i; j]$ of the square matrix M .

To minimize the sum of the costs in the assignment, the optimum value is given by $L. + M$, since the summation $+/$ is applied to each of the $11 \div PM$ possible assignments, and the minimum $L./$ is applied over them.

Other useful function pairs in assignment type problems include $\Gamma. + M$, $L. \times M$, $\Gamma. \times M$, $L. \Gamma M$, and $\Gamma. LM$.

A square Boolean matrix B is said to be a *Latin square* if it contains exactly $1 \div PB$ ones, with one in each row and one in each column; one Boolean matrix C is said to *cover* another, D , if $\wedge /, C \geq D$. The expression \vee, AC yields 1 if C covers a Latin square, and the expression $+, AC$ tells how many distinct Latin squares are covered by C .

7 Verb Formation

This chapter describes the various mechanisms by which you enter the definition of a user-defined verb or edit the definition once it has been entered. To write your definition appropriately, and to edit it when it runs into trouble, you will also need to be aware of the way a definition is used, how names are localized, what happens when an error or interrupt is encountered, and how such events can be handled automatically. These topics are covered in Chapter 8, "Control of Execution" and Chapter 9, "Event Handling"; you may need to consult those chapters in order to elucidate some of the points raised in this one.

Mechanisms for Defining and Editing Verbs

APL has three main syntactic classes: nouns and pronouns, verbs; adverbs and conjunctions. Members of these classes are formed and named in different ways.

- A **noun** is assigned a name by the *copula*, denoted by the left-pointing arrow \leftarrow . See Chapter 4, "Naming Nouns and Pronouns".
- An **adverb** or **conjunction** exists only as a primitive and may not be given a name. Currently, there is no mechanism for creating user-defined adverbs or conjunctions.
- A **user-defined verb** is produced by either of two routes:¹
 - *The definition editor.* Because you invoke the editor by entering the symbol `V`, it is called the *V-editor* or *del-editor*.
 - *The system verbs* `⎕fx` and `⎕fd`. Each of these takes as argument an array of characters that represent the definition of the verb to be created. You can edit an existing verb by capturing its present definition with the verb `⎕cr` or 1 or 2 `⎕fd`, editing the resulting array, and then using `⎕fx` or 3 `⎕fd` to create a new definition that replaces the old.

In addition to these ways of creating a new definition, a previously defined pronoun or verb may be materialized in the workspace by:

- *Copying is from a saved workspace* by means of the command `⋄copy` or `⋄pcopy`, described in Chapter 12, "System Commands". The copied verb creates or replaces the *global* referent

¹ Executing an adverb or conjunction also produces a verb. However, the *derived* verb thus produced cannot currently be assigned a name and thus exists only as passing, during the execution of a sentence that contains an adverb.

of the name. The `)copy` or `)pcopy` commands will not replace a verb that appears anywhere on the state indicator, and hence cannot be used to edit a verb that is in use.

- *Defining it from within a package* by means of the system verbs `⌈pdef` or `⌈ppdef`, described in Chapter 11, "System Nouns and Verbs". The verb thus defined creates or replaces the *local* referent of the name. `⌈pdef` and `⌈ppdef` will not materialize an object while an object of the same name is visible anywhere on the state indicator, and hence cannot be used to edit a verb that is in use.

	v-Editor	System verbs <code>⌈fx</code> or <code>⌈fd</code>
Invocation	<i>Interactive.</i> You can invoke the editor only while your session is in <i>immediate execution</i> mode.	<i>APL primitive.</i> Either system verb may be included in any APL sentence being executed.
Name Localization	<i>Global.</i> The v-editor always creates or edits a verb having a <i>global</i> name and ignores any local use the name may have.	<i>Local.</i> Either <code>⌈fx</code> or <code>⌈fd</code> creates a verb whose name is at the <i>visible</i> (that is, most local) level. When the proposed name has not been localized, the most local level is the same as the global level; in that case, the v-editor and the verbs <code>⌈fx</code> and <code>⌈cr</code> affect the same object.
Editing During Suspension	<i>Suspended verbs.</i> You can use the v-editor to edit a verb whose execution is <i>suspended</i> – that is, its name appears in the state indicator <i>with</i> an asterisk beside it. You <i>cannot</i> use the v-editor when the verb is <i>pendent</i> – that is, when its name appears anywhere in the state indicator <i>without</i> an asterisk.	<i>Any verbs.</i> Either <code>⌈fx</code> or <code>⌈fd</code> can redefine any verb provided the verb is visible. (However, it is possible to make certain changes that will prevent resumption of work on verbs that are pendent; see "Damage to a Pendent Verb," below.)

Figure 7-1: Comparison of v-editor and `⌈fx` or `⌈fd`.

Representation of a User-Defined Verb

The *standard form* for display of a user-defined verb, used by the ∇ -editor and returned by the system verb 1 $\square f d$, marks a definition by the symbol ∇ at the beginning and end. Each line of the definition is assigned a number, shown at the beginning of each line in square brackets.³ For example, here is the standard display of a definition for a user-defined verb called *growthrate*:

```

       $\nabla$  z←time growthrate rate;r;t
[1]   r←0.01×rate÷12
[2]   →(2=□nc 'time')/dyad
[3]   monad:t←time÷1
[4]   dyad:t←time×12
[5]   z←(1+r)×.×t

```

Each definition consists of a *header* (the top line) and a *body* (the rest).

Header The top line names the verb and illustrates its syntax. In the display, the top line has no line number; during editing, you refer to it as line [0]. By convention, the final ∇ appears on a line of its own.

Body The header is followed by a sequence of numbered lines called the *body*. The body shows the APL sentences the system should execute when the function is invoked. The APL system supplies the line numbers itself; it numbers the lines with consecutive integers starting at [1].

Canonical Form

The *canonical representation* of a definition lacks the bracketed line numbers and the opening and closing ∇ , but is otherwise the same. It is displayed flush-left:

```

z←time growthrate rate;r;t
r←0.01×rate÷12
→(2=□nc 'time')/dyad
monad:t←time÷1
dyad:t←time×12
z←(1+r)×.×t

```

The canonical form is returned (as a table) by the system verb $\square cr$ or by 2 $\square f d$ (see Chapter 11, "System Nouns and Verbs").

³ The spacing on each line is generated by the system afresh each time a verb's definition is displayed, according to a standard convention. Because of that, redundant blanks that you may introduce when you enter the definition are discarded in the display.

The system verb `⌊fx` expects an argument in the canonical form. The system verb `3 ⌊fd` accepts either the canonical form (as a table) or the standard form (as a list with embedded *newline* characters, with line numbers and opening and closing `▽`).

Names in the Header

The header always contains the verb's name. This is the name by which the verb is invoked in an APL sentence. In the example, the verb's name is *growthrate*.

The header also indicates whether the verb takes arguments and returns a result. It does so by supplying names by which the argument and result are known inside the definition. When the verb takes *one* argument, a name for the argument follows the verb's name. In the example, *rate* is the way the verb refers to its right argument.

When the verb takes *two* arguments, names for the arguments appear one on either side of the verb's name. In the example, *time* and *rate* are names for the two arguments.

When the verb returns an explicit result, the header includes a name for the result. The result (if present) must be the first name in the header, and must be followed by the copula. In the example, *z* is a name for the result. When execution of the verb terminates, the result returned is whatever value has been assigned to the name shown in the header as the result.

If the header does not provide for a result, or execution terminates without assigning a value to the name that the header designates for the result, the verb can still be executed. However, when the sentence that invokes the verb tries to make use of the verb's (nonexistent) result, APL reports a *result error*. Thus, a verb that returns no result can be executed only when it is the sentence's root verb.⁵

Headers for Monadic, Dyadic, and Ambivalent Verbs

A *monad* is a verb that takes one argument. The header of a verb that can be used only as a monad therefore provides a name for only one argument. The name for the argument follows the name of the verb.

An *ambivalent* verb can be used either as a monad or as a dyad. A user-defined verb whose header provides names for two arguments is ambivalent, and may be used with one argument or with two. When you use the verb dyadically, you must place its arguments around it, one on each side of the

⁵ For discussion of the root verb, see the sections on order of execution in Chapter 2, "Grammar".

verb. Inside the definition, the values supplied as arguments are referred to by the names shown in the header.

When you use an ambivalent verb monadically, you place the argument *after* the verb. Immediately to the verb's left, there must be no noun that could be its left argument.⁴ Inside the definition, the value you supplied for the right argument is known by whatever name appears in the header to the right of the verb's name. The name to the left of the verb's name is reserved for the left argument. During monadic use, that name has no value. A verb intended for ambivalent use should therefore test for the existence of the left argument (as, for example, in line 2 of *growthrate*).

Localization of Names

Except for the name of the verb itself, every name that appears in the header is thereby declared to be a *local* name. In particular, the names for the verb's arguments and result are local names. *Inside the definition*, those names are used to refer to the nouns supplied as the verb's arguments.

The names used as *labels* for lines within the definition are also local to the definition. (In the example, *monad* is a label for line 3, and *dyad* is a label for line 4.)

A label is a name that occurs at the beginning of a line and is separated from the rest of the line by a colon. While the verb is being executed, the name has a value equal to the number of the line to which it is attached. Thus, during execution of *growthrate*, *monad* has the value 3 and *dyad* has the value 4. Although a label can be used in the same way as any other noun (for example, to compute *monad+1*), its value is fixed; you cannot assign a new value to a label.

Additional local names may be declared by listing them in the header, to the right of the names for the verb and its arguments and set off by semicolons. In the example, the names *r* and *t* are localized. This means that, during execution of *growthrate*, the only visible uses of those names are the ones assigned by *growthrate*. After execution of *growthrate* is complete, all local meanings of those names disappear and their prior (more global) meanings – if any – are again visible.⁵

⁴ A noun that is to the verb's left but is the argument of a conjunction does not count. For example, in the phrase *a+2 ambiverb x*, the number 2 is not available to be the left argument of *ambiverb*, and so the verb is here used as a monad.

⁵ The name of the verb itself is not local. You could make it local by including it in the list in the header or using it as a label. When you make the verb's own name local to it, you make it impossible to invoke the verb again until execution from the first invocation is complete.

Using the ∇-Editor

When you are in immediate execution mode, entering a line whose first non-blank character is ∇ switches you to definition mode. You remain in definition mode until you enter a line whose last non-blank character is ∇. (A ∇ embedded in a phrase or inside a character constant or a comment does not count.)

What you enter with the ∇ depends on whether you are defining a *new* verb or editing an existing verb definition.

New definition ∇ *z-myverb price;subtotal*

Enter ∇ followed (on the same line) by the verb's header. The header *must* include the verb's name. It should also include a name for the verb's result, its arguments, and its local names (as illustrated above or in the example for *growthrate*). If you are not sure of some of these names, you can put in just the ones you already know and use the editor to supply the other names later.

Existing definition ∇ *myverb*

Enter ∇ followed by the *name* of the verb (with no mention of its result, arguments, local names, etc.).

Prompts in the ∇-Editor

The editor prompts by entering the number of the next line (in brackets). When you are just starting a new definition, the "next" line is line 1; so for a new definition the initial prompt is [1]. For a definition that already has three lines, the initial prompt is [4].

To the right of the prompt, the editor waits for you to enter the text you want on that line, or an editing command. An editing command starts with [, or). A line of text whose first non-blank character is something other than [,), or ∇ becomes the definition of the line whose number the system displayed at the left.

If you want to change the line number, use can either edit it just like any other part of the line, or enter a new line number after the existing line number prompt.

Editing Commands

- [*n*] Define (or redefine) line *n*.
- [*Δ n1 n2 ...*] Delete lines *n1*, *n2*, ...
- [*□*] Display the entire definition.
- [*n□*] Display line *n*.
- [*□n*] Display from line *n* to the end.
-) Copy the last immediate-execution line.
- [*n□□*] Edit line *n*. Leaves the cursor at the end of the line. You may backspace and overwrite or insert corrections.

Interpolating Lines Between Existing Lines

You interpolate a line by giving it an interpolated line number. For example, to insert a new line between lines 3 and 4, enter [*3.1*] (or any other fraction greater than 3 and less than 4).

While you continue editing, the editor leaves the lines with whatever numbers you assign them. But when you leave the editor (thereby closing the definition), the editor rennumbers all lines with consecutive integers.

Once you have entered a line, the editor prompts for the next line in sequence. It does that by adding 1 to the last position used in the line just completed. When the previous line had an integer line number, the editor's next prompt is 1 more than that. When the previous line was a fraction with two decimal places (for example, [*6.02*]), the editor adds .01, so its next prompt is [*6.03*]. It may prompt for an existing line number, so be careful not to enter an inserted line over an extant one.

Empty Lines

Empty (all blank) lines cannot be entered using the editor. Although empty lines are accepted within APL functions, they can only be entered using the system verbs *□fx* and *3 □fd*. The editor will, however, allow display or deletion of empty lines.

Syntactically Invalid Lines

Lines which are syntactically invalid are accepted by both the editor, and by the system verbs *□fx* and *3 □fd*. Syntactically invalid lines include those which contain unbalanced quotes, third alphabet characters not in quoted strings, invalid numeric constants, and invalid system noun or system verb names.

Box-drawing Characters

The system verbs `⎕fx` and `3 ⎕fd` allow you to enter lines which contain the box-drawing characters (`⎕av[241+111]`) in quoted strings. The `▽`-editor will allow you to display or delete such lines, but does not permit their entry.

Editing Occurs in Real Time

You cannot "quit" the `▽`-editor, as you usually can do with text editors. Each line of the verb is altered as you enter that line. If you have made an error in editing a verb, the best approach is to obtain a fresh copy of the verb (perhaps by) *copy* from a saved copy of the workspace) and start `⎕vmm`.

Closing the Definition

When you are satisfied with what you have entered, you enter `▽` to indicate that editing is complete. The character may stand alone, or it may appear at the right end of a line you have just entered. The editor rennumbers the lines with consecutive integers and creates the newly defined verb.

When you edit a previously existing verb and change its name by editing line 0, closing the definition both creates the new definition and erases the old.

Locking the Definition

If you exit from definition mode with `▽` rather than `▽`, the definition is both closed and locked. The editor rejects an attempt to use the `▽`-editor on a locked definition with the message *defn error*. The system verbs `⎕cr` or `⎕fd` simply return an empty array as the definition of a locked verb. Furthermore, the text of the line will not be displayed in error reports nor will it appear in `⎕er`.

The APL system provides no means to unlock a locked verb once you have locked it. It is prudent to keep somewhere safe an unlocked version of any verb you lock.

Editing Can Prevent Resumption of Execution

One of the very useful features of an APL system is that when a user-defined verb encounters an error, execution halts but is not abandoned. You can correct the definition and resume execution without having to abandon the work already done. (see Chapter 8, "Control of Execution".)

However, editing the definition of verb while it is being executed (that is, editing a verb whose name appears on the state indicator) has some risks. It is possible to modify the definition in such a way that you cannot resume execution of the verb you edited, or so that it is no longer possible to return to the verb that invoked it. Problems created by editing a verb whose execution has not terminated are lumped together under the name *state indicator damage*. Attempting to resume execution of a verb whose definition has been rendered inaccessible or ambiguous is rejected as event 9, *sl error*. This event can be trapped, but recovery may require cutting back the stack (abandoning the more recent work) and resuming from an earlier point. (see Chapter 9, "Event Handling")

Distinguishing Active, Pendent, and Suspended Verbs

In discussing the effects produced by changing the definitions of verbs before they have finished, it is useful to distinguish three situations. A verb may be *active*, *pendent*, or *suspended*. Here is what these terms mean:

Active The condition of the user-defined verb now being executed. Its name is at the top of the execution stack. The state indicator (reported by 2 `□ws 2`) shows no asterisk beside its name because it is not halted.

This is a situation you can never see from immediate execution. Since the V-editor can be invoked only from immediate execution, it can never edit the active verb. However, `□fx` and 3 `□fd` are permitted to edit the active verb.

Pendent The condition of a user-defined verb that has invoked another user-defined verb. The pendent verb is waiting for the verb it invoked to complete execution. When that happens, the pendent verb automatically becomes active again. Until then, it has nothing to do. It is waiting in mid-line (since it has started execution of a line in its definition but has not yet completed that line).

Suspended The condition of a verb whose execution has been halted because of an error or interrupt. A suspended verb is marked in the state indicator by an asterisk.

When a verb's execution is interrupted, the system looks for a `□trap` expression or `□ec` to tell it what to do next. If it does not find a trap that covers the event, it displays a message describing the event and reverts to immediate execution mode. Now if you execute the command `)sl`, you will see the verb's name at the top of the stack with an asterisk beside it.

Damage to the Active Verb

It is possible for the active verb to modify itself by a statement that uses `⌊fx` or `3 ⌊fd`. When redefinition changes the line being executed, APL reports an *si* error. A change is considered to have occurred when, following use of `⌊fx` or `3 ⌊fd`, the line whose number is reported in the first item of `⌊lc` is no longer identical to the line the interpreter started with. That could arise either because:

- you actually changed that line
- or*
- you inserted or deleted lines ahead of it so that the first element of the line counter now points to a line with different content.

When APL detects such a change to the current line of the active verb, it replaces the verb's name in the state indicator by blanks and signals event 9, *si* error.

Damage to a Pendent Verb

The name of a pendent verb appears in the state indicator without an asterisk. (The active verb is a special case of a pendent verb.)

The active verb's use of `⌊fx` or `3 ⌊fd` may damage a pendent verb in the same way as it may damage the active verb itself: by changing the sentence to which the line counter points. When the active verb completes execution and attempts to return control to the pendent verb, the interpreter signals event 9, *si* error.

APL may be unable to resume execution of a pendent verb if you change the localization of its name in a way that makes the verb invisible. That can happen in either of two ways:

- You localize the verb's name.
- The verb's name is initially local, but you delocalize it.

In either case, APL replaces the verb's name in the state indicator by blanks. It leaves `⌊lc` unchanged. When the pendent verb completes execution and tries to return control to the verb that invoked it, it finds the name is now blank. It signals event 9, *si* error.

When work is suspended and the top row of the state indicator contains a verb whose name is blank, a branch statement in the recovery expression of a relevant `⌊trap` (or a branch statement entered from the keyboard) causes a normal exit (but with no result). That line is removed from the state indicator, and control passes to the line that followed it. That line may be able to resume — provided it is not expecting a result.

8 *Control of Execution*

This chapter describes how you “run” a program — that is, start the execution of a sentence containing a user-defined verb. It describes what happens as that verb uses other user-defined verbs and how they refer to nouns to pass data between them. It also describes what happens when the program encounters an error or is interrupted, how you can make changes or corrections to the suspended program, and how you can resume work without having to start over from the beginning.

Programming and Immediate Execution

In its default state, APL is an interactive system. That is, when you start an APL session from a keyboard, the APL system waits for you to type one sentence from the keyboard. When you signal that your sentence is complete (by pressing the *Enter* key), the APL system interprets and executes that sentence and displays its result. Then it waits for you to type another.

If each of the sentences you type is a small calculation, you get the answer immediately; the session is a rapid alternation between question and answer.

However, the sentence you type may invoke a user-defined verb (or several of them, in a compound sentence). The verb's definition may contain up to 32767 lines. Each of the sentences on those lines may itself invoke other user-defined verbs. They in turn may invoke others. Thus a single sentence you enter from the keyboard may set in motion a great deal of work.

A verb's definition consists of a sequence of APL sentences. In principle, anything a program does you could also do by entering instructions from the keyboard. You could simply enter each sentence, watch it execute, and then enter the next.¹ A verb's definition thus consists of a set of sentences that you *might* have entered from the keyboard for immediate execution. Instead, you — or someone — entered them earlier and made them part of a definition. Perhaps you used the *V*-editor to accumulate them, or perhaps a word processor. Perhaps you acquired the whole set of definitions simply by entering the command `)load` followed by the name of a saved workspace and thereby gained access to any of the definitions stored in it. Perhaps

¹ There are a few things that occur only within the environment of a user-defined verb and thus cannot be done solely by entering instructions from the keyboard for immediate execution. For instance, the localization of names is a property of a user-defined verb. The environment condition `Loc` assumes a default value when made local to a user-defined verb. These could be manipulated by expressions typed from the keyboard, but only while a user-defined verb is suspended. See the discussion of `Loc` in Chapter 9, “Event Handling”.

you have a `Qtrap` set up so that each time you or your program asks for something that is not now defined, it retrieves what is needed from a file.

Once you have the definitions for a program, you instruct APL to execute the program simply by including its name in a sentence to be executed.

Status of Work in Progress

Each workspace contains a *state indicator* and a *line counter*. Together, these show the name of the verb now active and the line of that verb now being executed. They also show the verb that invoked the active verb, and the verb that invoked it – for as many verbs as are involved. The state indicator contains a row for each defined verb whose execution has started but not yet completed. It also shows the symbols `Δ` and `□` in the same manner as user-defined verbs.

When no user-defined verb is pending, the state indicator is empty. When you enter a sentence containing a user-defined verb, the name of the verb to be executed goes on the state indicator. At the same time, the line counter keeps track of the number of the line that is now being executed (or that is ready to execute, when the interpreter is between lines).

If, before work on that verb is complete, its definition invokes another user-defined verb, that verb's name is added as a new row at the top of the state indicator. APL sets aside work on the row below and focuses on the row at the top. When it finishes work on that top row, it removes it from the state indicator stack and resumes work on the row that was temporarily pushed

away.

The command `⍝si` (*state indicator*) shows the names that are on the state indicator stack, commonly just called the *stack*. You can only enter a system command when your task is in immediate execution mode. Thus the command `⍝si` has something to show you only when work has been interrupted, leaving the names of some user-defined verbs on the stack. The system verb `2 ⍝ws 2` reports the same information. However, since `2 ⍝ws 2` does not require a return to immediate execution, it can report what is on the stack as it goes along. To illustrate, consider the following two programs:

```
⍝ z←verb1
[1] 'This is verb 1, and here is si:'
[2] 2 ⍝ws 2
[3] z←⍝si
[4] z←z,verb2
⍝
```

```
    ▽ z←verb2
[1]   'This is verb 2, and here is si:'
[2]   2 ⌈ws 2
[3]   z←⌈⌋lc
```

When you execute *verb1*, you see first the state indicator as it was when line 2 of *verb1* was active, then the state indicator as it was during the corresponding line of *verb2*, and finally the result:

```
    verb1
This is verb1, and here is si:
verb1[2]
This is verb2, and here is si:
verb2[2]
verb1[4]
1 2
```

The result *1 2* is the number of *itcrs* on the state indicator during execution of *verb1* and *verb2*.

Suspension Due to Error or Interrupt

Something may happen that prevents completion of the execution of a verb. Something in the environment may be unsatisfactory (a file is not available, or there is not enough space in the workspace). Something needed may be missing (a utility verb may be invoked but not present). The definition itself may contain an error of spelling or syntax.

Work may also be suspended by a signal from outside. You can signal an interrupt at two levels of urgency:

Weak interrupt Signaled by a single press of CTRL+break. Requests APL to halt before beginning the next line of a user-defined verb.

Strong interrupt Repeating the signal upgrades a former weak interrupt on which APL has not yet acted. It becomes a strong interrupt. It requests a halt to processing as soon as possible, without waiting for the start of the next line, or even for completion of the current line.

In general, after encountering an error or receiving an interrupt signal, APL stops working on the sentence that is now active. The interpreter checks to see whether the condition is provided for in an *event trap* (described in the next chapter). If no trap is provided, APL halts, but does not abandon

execution. It notes where it is in the active program. Then it returns to immediate execution mode and awaits further instructions.

You are free to take corrective action and then resume work. Or you may do something else for a while and then take corrective action and resume work. Or you may abandon execution of the most recent keyboard entry by entering `→ alone`, or abandon all executions by entering `)sic` (*state indicator clear*).

When you save your active workspace, the line counter and state indicator are saved as part of it. When the saved workspace is loaded at some later occasion, it is recovered as it was, including the state indicator showing where it is in the verbs you left partially executed. If it is appropriate, you will be able to resume execution where it was suspended.

Pendent vs. Suspended Verbs

A verb whose execution has stopped because of an interruption or an error is said to be *suspended*.

A verb whose name is in the state indicator but is *not* suspended or active is said to be *pendent*. Although it is not currently active, nothing is wrong with it; it is simply waiting until execution of the verb that it invoked is completed. Execution of a pendent verb resumes automatically as soon as execution of the verb above it in the state indicator is completed.

The result of `2 Dws 2` (or the display produced by `)si`) shows on each row the name of a verb, followed in brackets by the number of the current line for that verb. A suspended verb is marked by an asterisk, whereas a pendent verb has no asterisk.

The Line Counter

The system noun `□lc` returns a numeric vector having one element for each row of the state indicator; it contains in numeric form the line numbers shown in brackets in the display of the state indicator.

For a pendent verb, the line number shown is the number of the line now being executed. For a suspended verb whose execution was halted by an error or interrupt, `□lc` shows the number of the line the system was executing when the error or interrupt occurred. For a verb halted after execution of one line has been completed, but before execution of the next line has started, `□lc` shows the number of the line next to be executed if execution is resumed in sequence.

When the system puts the symbol `*` or `□` on the state indicator, the corresponding element of `□lc` contains the line number of the verb that contains

the Δ or \square . When you enter Δ or \square from the keyboard (in immediate execution), the corresponding element of $\square 1 c$ contains the line number of the most recently suspended verb. However, for Δ when no user-defined verb is on the state indicator, $\square 1 c$ contains 0.

Local Names at Each Level of the State Indicator

Each user-defined verb may declare that certain names are *local* to its definition. The local names are those used in the header to name its arguments and its result, and those listed further to the right, set off by semicolons. A verb's *line labels* are also local.

However, the name of the verb itself is not local unless that name is explicitly repeated in the list of local names, or is also the name of a label, an argument, or the result.

As long as a verb works satisfactorily, you never need to know what names within it represent its arguments or its result, or what other names it may localize. These become significant *only* when you halt the verb or change its definition.

The command `)sinl` (*state indicator with name list*) shows the same information as `)sl`, but lists on each row the names that are localized at that level.

To illustrate the effects of localization, suppose that there exist in the workspace three objects called *a*, *b*, and *c*. Suppose that you invoke a verb named *verb1*, whose line 4 invokes *verb2*, whose line 3 invokes *verb3*, whose line 7 invokes *verb4*. Suppose that *verb4* refers to all three names, *a*, *b*, and *c*.

The definitions are written so that *verb1* and *verb4* each localizes the name *c*, while *verb3* localizes the name *b*. If you halt execution of *verb4* (while it is working on line 2) and display `)sinl`, it looks like this:

```
)sinl
verb4[2] * c
verb3[7] b
verb2[3]
verb1[4] c
```

To make clear how localization determines what referent is visible, Figure 8-1 arranges all names of interest so they are aligned in columns. What is visible at a particular instant is the view looking downward from the top row of the display produced by `)sinl`. For this purpose, the "global" level

is a row below the last row of `)sinl`, containing all names that are visible when no verb is being executed.²

Figure 8-1: The visible referent of a name is the first appearing in `)sinl`.

As you can see in Figure 8-1, since the name `a` is not localized by any of the verbs, a reference to `a` in `verb4` goes all the way down to the global level.

Since the name `b` is localized by `verb3`, a reference to `b` in `verb4` gets the `b` belonging to `verb3`. The local use of `b` is said to *shadow* the global `b`.

Since the name `c` is localized by `verb4`, a reference to `c` in `verb4` gets the `c` belonging to `verb4`, which shadows both the local use in `verb1` and the global `c`.

The system verb 5 `Qws` reports similar information. However, it reports it as a table in which there is a row for each name and a column for each level of the state indicator. You give it a list of names, and it reports the status of each name at each level, plus an extra column for global status. (See the description of `Qws` in Chapter 11, "System Nouns and Verbs".)

Dynamic Localization

The localization rule described in the preceding section is known as *dynamic localization*. That is, the names that a verb localizes appear global to the verbs it invokes.

² Strictly speaking, the bottom row of the figure should also show columns for the names `verb1`, `verb2`, etc., since those names are visible when no verbs are being executed.

Steps at the Start of Execution of a User-Defined Verb

Arguments are passed to a verb, and results returned, *by value*. A verb's argument is whatever noun is produced by evaluating the expression to the right or left of it. When the system starts to execute a defined verb, the following things happen:

- APL puts the verb's name at the top of the state indicator.
- APL appends a new item to the front of `QIC`, indicating which line in this verb is next to be executed. Initially, this number is 1. Later, as execution of the verb progresses, the number in `QIC`'s first item is revised so that it always shows the line now being processed or ready to be processed next. The first member of `QIC` always refers to the verb most recently started.
- APL prepares names for the values of the arguments. It does not matter by what names the arguments were known outside the verb (or even whether they had names at all). The names of the arguments are local. So are any other names mentioned in the header.
- APL prepares a name corresponding to each label and gives it a numeric value indicating the line to which it is attached. A label differs from other local variables in that:
 - it gets its value automatically at the start of verb execution
 - its value cannot be changed.
- All other names appearing in the verb header are local. That is, they have no referent until assigned one during execution of the verb.

Any object outside the verb, but having the same name as an argument, result, label, or local name of the verb, is invisible while the verb is being executed and is unaffected by any action performed while the verb is active.

APL executes the lines of the verb in sequence (or as branch statements may direct) until the verb ends. At that point, the value of whatever variable was named in the header as the result of the verb is returned. The first element of `QIC` is dropped and the verb's name is removed from the state indicator. The referents of all names local to the verb vanish. The earlier (more global) referents of those names (if any) become visible once more. If a previous line on the state indicator indicated a pendent verb, it would become active again.

Example of Argument and Result Passing

Chapter 7, "Verb Formation" showed a verb *growthrate* to illustrate the standard form of a definition. The left argument was the number of years for which monthly compounding continues, and the right argument the annual percentage rate of interest. In the definition, the left argument was called

time and the right argument *rate*. Suppose a verb *report* contains on line 3 the sentence:

```
Total←Inv×Years growthrate BaseRate÷0.5×16
```

As APL starts on this sentence, the state indicator contains:

```
report[3]
```

In processing the sentence, APL finds that the verb *growthrate* is a dyad. When APL has found the value of *Years* and the value of *BaseRate*÷0.5×16, it invokes the verb *growthrate*. It leaves *report*[3] pendent while it puts a new verb at the top of the state indicator.

If at that point you could see the state indicator with name list, it would appear thus:

```
growthrate[1] z rate time dyad monad  
report[3] z Total Inv Years BaseRate
```

As soon as *growthrate* is placed on the top of the state indicator, APL reserves the local names you can see beside *growthrate*[1]. The labels *monad* and *dyad* are given the values 3 and 4 respectively.

The right argument *rate* receives as its value the array that results from evaluating *BaseRate*÷0.5×16.

The left argument *time* is assigned the value of the array *Years*.

The name *z* is given no value; it is reserved for the result.

Multiple Copies of Arrays Share the Same Space

In this example, when *growthrate* is invoked, its left argument is not an expression but simply the name *Years*. Since *Years* already exists and the new name *time* is to have the same value, APL simply notes that *time* is the same as *Years* and does not create a second copy of the data. However, if the definition of *growthrate* subsequently sets a new value for *time* (for example, by a sentence such as *time←time*×12), APL then gives *time* its own value and no longer refers to the value of *Years*.

In general, whenever a name is assigned a value already identified by another name (for example, in an expression such as *x←y←z←1n*), APL creates only a single data array and lets all the other names refer to it, rather than making many copies of the same array. As soon as there is any change to any part of the value assigned to any of the names, APL creates a separate copy of the entire object for that particular name. This aspect of internal housekeeping is not directly visible other than by its benefits in reducing

the requirements for storage in the active workspace, and a reduction in the time required to perform the operation.

Many expressions in APL involving verbs and derived verbs save time and space in this way when their result is the left or right argument. Such expressions are called *identities*. For example, *ravel* of a list does no actual data movement. It takes fixed time and space to execute, regardless of the size of the argument.

Value Returned by the Verb at Completion

When execution of *growthrate* is complete, the name *growthrate* is removed from the top of the state indicator and APL picks up where it left off in its evaluation of line 3 of *report*. As *growthrate* terminates, APL notes the name assigned to its result (in this case, *z*). Whatever value *z* then has is returned to the statement that invoked *growthrate*. Thus, in the example, whatever value *z* then had becomes the value for the right argument of *x*.

Branch Controls the Sequence in Which Lines Are Executed

Unless a branch statement (see next section) modifies the order, APL executes the lines in a verb's definition one after another in ascending numeric order starting with line 1.

A sentence whose first non-blank character, not counting a label and its colon, is the right-pointing arrow \rightarrow , is a *branch statement*.

A branch statement overrides the normal sequence of execution by telling APL the number of the line to execute next. A branch can also be used to resume suspended execution, either manually from the keyboard or as part of an automatic recovery set up by *Qt rap* (described in Chapter 9, "Event Handling"). A suspended verb can be restarted only at the beginning of a line (even though the interrupting event may have occurred in mid-line).

A branch affects *only* the verb at the top of the state indicator.

When execution is suspended, entering a branch statement from the keyboard causes the verb at the top of the state indicator to resume execution at the beginning of the line indicated in the branch statement.

Form of a Branch Statement

The branch arrow \rightarrow may stand alone or may be followed by an expression. The expression to the right of the arrow is the *destination* of the branch. When evaluated, the destination must be an item or a list. When the list

is not empty, its *first* element must be an integer. APL rejects any other value as event 11, *domain error*.

The expression to the right of the arrow is usually stated as some function of one or more of the verb's line labels, or 0 (meaning "exit"). However, the statement is not *required* to refer to a label. A label is a handy way of referring to a line's number. Labels also improve the maintainability of APL programs.

Result and Effect of a Branch

Branch is not a verb and does not have a result.

When the destination of a branch identifies an existing line, control passes immediately to that line. When the destination is a list having more than one item, items after the first are ignored.

Effect When Destination Is Zero or Out of Range

A destination that is an integer but is *not* the number of any line in the current verb (typically, 0) forces a normal end to the verb's execution. The verb returns whatever value has by then been assigned to the name that appears to the left of `←` in the header.⁹

When the *exit* occurs before the result has been given a value, the verb returns no result. If the sentence that invoked the verb needs the verb's result, the failure to return a result causes event 8, *result error*.

Effect When Destination Is Empty

During execution of a user-defined verb, branch to an empty destination has no effect. The empty branch may arise directly from

`→10`

or (more likely) from

`→(false condition)/label`

Following an empty branch, execution continues in sequence with the next sentence. (On a line with diamonds, that is the next sentence to the right. Otherwise, execution proceeds to the line below.)

When execution is halted, an empty branch does not restart it.

⁹ The system verb `⌈signal` also terminates execution of the active verb, but by forcing an abnormal end. The event identified in `⌈signal`'s argument is reported to the verb that invoked the active verb. See the description of `⌈signal` in Chapter 11, "System Nouns and Verbs" and the discussion of event handling in Chapter 9, "Event Handling".

Branch in Execute

The foregoing statements about branch remain true regardless of whether it occurs within the argument of *⌘* (*execute*). Thus

⌘→*dest*†

has exactly the same effect as

→*dest*

Branch in a Line with Diamonds

The foregoing statements about branch remain true regardless of where the branch statement is located within the line. For example, suppose a line contains three sentences separated by diamonds and a branch in the middle sentence, thus:

sentence1 ♦ →*elsewhere* ♦ *sentence2*

When the shape of *elsewhere* is empty, both *sentence1* and *sentence2* are executed. But when *elsewhere* is not empty, *sentence1* is executed and *sentence2* is not.

Branch to Resume Suspended Execution

When a verb has been suspended, the system waits for you to indicate what you want done with it. The system does *not* abandon the suspended verb. You do not have to resume execution at once; you are free to start execution of any verb whose definition is visible. (If you do so, those new verb calls appear at the top of the state indicator, above the entries showing the suspended verb.)

When execution of a user-defined verb is suspended (so that the suspended verb's name is at the top of the state indicator and has an asterisk beside it), a branch statement with a non-empty destination causes the active verb to resume execution at the line that is the branch's destination. The branch statement that resumes work:

- may be entered manually from the keyboard
- may be part of the recovery expression of a trap.[†]

Generally, when execution has been halted, the expression →□?⌘ resumes work. Note, however, the effects of a mid-line halt, discussed next.

[†] See Chapter 9, "Event Handling".

Resumption Following a Mid-line Halt

When the halt occurred between lines (for example, in response to a weak interrupt signaled from the keyboard) `⌞⌈c` causes execution to continue with the next line in sequence.

When the halt occurred in mid-line (for example, in response to an error or a strong interrupt), `⌈c` contains the number of the line on which APL was working. Part of that line may have been executed already. Execution always resumes at the *beginning* of a line. Therefore `⌞⌈c` resumes at the *start* of the line, even though part of it was already executed before the error or interrupt. The caret included with the error display (or in `⌈ar`) indicates how much of the line has already been attempted. Depending on what the line contains, repeating it from the beginning may be harmless or may be undesirable, leading to incorrect results. A line written so that restarting it from the beginning is always harmless is said to be *restartable*.

Naked Branch to Abandon Execution

A *naked branch* is a sentence in which the right-pointing arrow stands alone, with nothing to right of it, thus:

→

Execution of the active verb (that is, the verb at the top of the state indicator, regardless of whether it is running or suspended) is aborted, *along with the entire sequence of verbs that invoked it*.

APL removes from the state indicator the current top row (containing the name of the active verb) and any other verbs down to (but not including) the next verb marked with an asterisk.

Clearing the Entire State Indicator

The system command `⌞sic` completely clears the state indicator. Execution of all verbs on the state indicator is aborted.⁵

Branch During ⌈-Input

A naked branch within `⌈`-input acts in the same way as a naked branch during execution. That is, the evaluation of `⌈` is aborted and so is the entire sequence of verbs that invoked `⌈`.

Branch with a destination is not permitted during `⌈`-input. If you attempt it, the system rejects your entry with the message *result error* and reissues the request for `⌈`-input.

⁵ This command was formerly called `⌞reset`.

Calculating the Destination of a Branch

The effect of a branch depends on the numeric value of the destination, but not at all on the manner in which the calculation is stated. So there are a great many different ways to write branch expressions. The following examples illustrate only a few possibilities.

Conditional Branch

The destination expression includes a label and a test; the result is either empty (no branch) or the value of the label. The test yields either a 1 (condition is true) or a 0 (condition is false). The result of the test selects or ignores the value of the label, through compression, reshape, take, or drop. For example, to branch to *label* when *a* is greater than *b* could be written:

```
→(a>b)/label
```

A complementary pair corresponding to *if* and *unless* can be formed with *†* for *if* and *‡* for *unless*:

```
→(a>b)†label      «Branch to label if a>b
```

```
→(a≤b)‡label      «Branch to label unless a≤b
```

Conditional Execution of Statements on the Same Line

When you want to execute *work* only when *a* is greater than *b*, you could exit conditionally from the line, thereby executing *work* only when the destination is empty:

```
→(a≤b)/next ♦ work  
next: ...
```

The same effect could be achieved by

```
a(a≤b)/'work'
```

which may or may not be easier to read and may be less efficient to execute.

Multi-way Branch

Compression or indexing may select from among any number of alternatives. For example:

```
→((test1, test2, test3)/L1, L2, L3),default
```

or

```
→(label1, label2, label3)[test]
```

Branch with Counter

A simple loop often combines a conditional branch and an unconditional branch. The following shows a *leading decision* that controls n repetitions of a step called *work*. It is called a *leading decision* because the test is made before *work* is ever executed. That allows for the possibility that *work* may be executed zero times.

```
      i←0
test:  i←i+1
      →(n<i)/next
      work
      →test
next:  . . .
```

(Some people like to combine the test and the increment in a single statement, for example $→(n<i+i+1)/next$. However, in that form the statement is not restartable.)

Stop and Trace Controls

As an aid to debugging, you can set *stop-* or *trace-controls* for an unlocked user-defined verb. The two are independent but controlled by a similar mechanism. Stop and trace are effected by a dummy name composed of the characters *sA* or *tA* followed by the name of the verb. For example, to set stops on lines 3 and 15 of a verb called *work*, you execute:

```
sAwork←3 15
```

Similarly, to trace the execution of all lines of the verb called *work* that has no more than 99 lines, you might execute:

```
tAwork←199
```

The stop or trace is effective for those lines that actually exist and are assigned to the stop- or trace-control (so it is not wrong to assign 199 even when *work* in fact has only two lines).

Each time you set the stop-control for a verb, you thereby remove any previous stops. Similarly, each time you set the trace-control for a verb, you thereby remove any previous trace-controls. Once a stop or trace has been set, there is no mechanism to report the numbers of the lines on which it is effective.*

Stops and traces are removed by setting them to an empty vector:

* You could pass the result of $→$ to another program (and thereby record the values you used) by an expression such as `traced←tAwork←199`.

trawork+10

Stop and trace have no effect on locked verbs.

Effects of Stop

When APL comes to a line marked with a stop-control, execution halts *before* work on the line is started. The halt is event 1001. The effect is much the same as a weak interrupt signaled from the keyboard. That is, (provided the event is not trapped) execution is suspended at the beginning of the line. APL displays the name of the verb and the number of the line that is next to be executed.

You may examine the values of names, perform tests, edit definitions, and so on. When satisfied, you may resume execution at the point where work was halted by `⎕Jc` (or exploit any of the other options available when a verb's execution is suspended).

To permit the restart of suspended verbs, a line branched to from immediate execution is not subject to `sΔ`.

Effects of Trace

For each line for which a trace was requested, as APL completes execution of each sentence in the line, it displays a report. For the first sentence on each line, the report shows the name of the active verb together with the line number (in brackets). For subsequent sentences on the same line, it shows a diamond.

For each completed sentence in a traced line, APL displays the root value. For example, in a sentence such as

```
x←(a←15)×(b←22)
```

APL reports the value assigned to `x` but not the values assigned to `a` or `b`.

When the root value is an item or a list, it appears on the same line as the verb name and line number, or the diamond. When the root value is a table (or higher-rank array), the display starts on a new line (to preserve the alignment of columns).

When a sentence has no root value (because the root verb returns no result, or the line is empty), the trace display is blank.

When a sentence explicitly calls for display, APL first does the display in the usual way, and then the trace display as described in the preceding paragraphs (so tracing a line that itself produces a display will cause two displays).

When the traced sentence is a branch, the trace display shows the right arrow followed by the numeric value of the destination.

Effect of Editing on Trace or Display

Editing a verb's definition with the V-editor does not affect the stop or trace-controls. If you insert or delete lines ahead of the lines that are marked for stop or trace, tracing remains with the lines originally marked, even when they are renumbered.

The verbs `⌘fx` and `3 ⌘fd` in effect destroy the former definition and create a new one, so that editing a definition with either `⌘fx` or `3 ⌘fd` loses all of that verb's stop or trace settings.

Effect of Storing and Retrieving a Verb with Stop or Trace Set

A verb stored in a saved workspace retains the stop or trace settings it had in the active workspace and retains them when the workspace is loaded or when the verb is copied from the saved workspace.

A verb inserted into a package by the system verb `⌘pack` retains its trace or stop settings and they are retained when the verb is subsequently materialized from within the package by the system verb `⌘pdf`.

9 Event Handling

An *event* is something that disrupts the normal sequence of work and requires further instructions.

An event may be *trapped* or *untrapped*. An untrapped event returns control to the keyboard for you to take appropriate action.

A trapped event is one you have foreseen and provided for. The recovery instructions you store as part of a trap definition usually contain the same sorts of things you might otherwise enter from the keyboard after the event occurs. When they are stored in advance in `Trap`, the recovery proceeds automatically; there is no display of an error message and no pause to receive new instructions.

Errors and Interrupts

An event falls into one of two main classes:

Error APL is unable to carry out the sentence it is working on.

An error may arise for any of a number of reasons. For example, it might be because something is inherently wrong with the sentence itself (perhaps invalid syntax). The data supplied may be inappropriate to the verb (having the wrong type, rank, or value). The sentence may refer to a name that has not been defined. Alternatively, the problem may be that, although there is nothing wrong with the sentence, APL cannot execute it because of some constraint of resources (not enough room in the active workspace, file full, access denied, and so on).

Interrupt APL receives a signal from outside the active workspace indicating that work should be interrupted.

An interrupt arises from a signal from the keyboard: you press CTRL+break indicating that you want work halted, or press CTRL+c to interrupt input.¹

Classifying Interrupts

An interrupt is classified by what APL was doing at the time it halted execution in response to the interrupt. For example, if it was processing

¹ See the description of strong and weak interrupt in Chapter 8, "Control of Execution".

keyboard input, it calls the interrupt an *input interrupt*. The term *interrupt* (without a qualifying adjective) refers to an interruption during execution of an APL expression that did not involve something external to the workspace.

Weak and Strong Interrupts

In processing an interrupt, the system recognizes two levels of urgency. The first time you send an interrupt signal, the system notes a *weak interrupt*. A weak interrupt is also called an *attention signal*. APL takes a weak interrupt to mean "Halt before starting to execute a new line."

During the interval *after* you have sent the first interrupt signal but *before* APL has halted work, you may signal a second interrupt. When the system detects a second interrupt, it upgrades the urgency of your request and calls it a *strong interrupt*. Following a strong interrupt, APL halts as quickly as possible. It is very possible that the halt resulting from a strong interrupt occurs in the middle of a line, with some portion executed and some not. This may make the line non-restartable, in the sense that *side effects* may have occurred.

Signaled Errors

Executing the system verb `⌈signal` produces the same effect as an error. (`⌈signal` is limited to signaling errors; it cannot signal an interrupt.) In particular, `⌈signal`:

- Halts execution of the item at the top of the state indicator; that is, of the active user-defined verb or a use of `*` or `⌈input`. It also removes the item from the state indicator, causing the signaled error to be made visible to the verb which invoked the error-producing item. For a user-defined verb, this is equally true regardless of whether:
 - the active verb is running (that is, being executed)
 - or
 - the active verb is suspended, and you enter the sentence containing `⌈signal` from the keyboard.
- Sets `Der` to indicate the error number specified in the right argument of `⌈signal`. The optional left argument to `⌈signal` supplies the error text in `Der`.

You are free to use any error number between 1 and 999. That is, your use of `⌈signal` may either emulate a standard error (such as 11, *domain error* or 3, *index error*), or it may signal some arbitrary error unknown to APL but meaningful to your application. By convention, a user-defined

error is given a number between 500 and 999, whereas no system-generated error has a number in that range.

One reason for signaling a user-defined error is that you plan to trap it and thus provide automatic recovery from some condition that your application has signaled.

When `⌈signal` is used from within *execute*, or from within `⌈input`, the top line of the state indicator contains a or `⌈`. Then a or `⌈` is removed from the top of the state indicator (not the user-defined verb that contains it), and the event is signaled to the next level. Thus the effect of a `⌈signal n` is not the same as the effect of `⌈signal n`.

Trap, Action, and Recovery

An event trap is a list of instructions whose effect is to say to APL, "If the following occurs, here is what to do." The trap specifies what event (or events) to look for and an action code specifying what action to take when one of them occurs.

You write these instructions by setting the value of the system noun `⌈trap`. As soon as you set a value for `⌈trap`, APL verifies that `⌈trap` contains a valid action code and well-formed event numbers. (If APL finds your `⌈trap` ill-formed or otherwise invalid, it resets `⌈trap` to be an empty list.) Apart from that initial check for an ill-formed trap, setting `⌈trap` has no effect until a trappable event occurs. Then APL looks in the various values of `⌈trap` for an event number that matches the event that has occurred.

When you set `⌈trap`, you may supply any number of separate statements about events and actions. See the description of `⌈trap` in Chapter 11, "System Nouns and Verbs".

Unreportable or Untrappable Events

Certain events are outside the scope of the event handling mechanism. In particular, nothing that occurs during execution of a system command can generate a reportable or trappable event.

An error *directly* encountered during execution of a recovery expression is not itself trappable. This restriction prevents endless recursion from certain defective `⌈trap` expressions. However, even with this feature, it is still possible to construct event handlers that execute endlessly, so prudence is called for in their creation. Furthermore, errors occurring during the execution of a user-defined verb invoked by a `⌈trap` expression are trappable.

Event 2001 (return to immediate execution) is not reportable – that is, does not set a new value for `⌈er`, even though it is a trappable event.

Events 67 and 68 (certain system errors) are reportable – that is, *do* cause `⌈er` to be set, even though it is not feasible to do anything about them. They are not trappable, except when generated via `⌈signal`.

An event arising during execution of a system command is never reported in `⌈er` and cannot be trapped.

Environment Condition Prohibits Suspension

There arise cases in which you do not want a verb to be suspended. For example, in a shared nouns application, you do not want to permit one user, by interrupting a verb, to tie up another user. To preserve the security of data in a shared file, you do not want a user to be able to examine nouns before the verb has completed its processing. One way to prevent a verb from being suspended is to trap the events that might suspend it. However, such a trap can take effect only when it has been set and only when its recovery expression deals successfully with the event. Suppose the event occurs in the interval after the verb has started execution but before a trap has been set. Suppose that when the event occurs, it is something for which the trap makes no provision. `Dec` (for *environment condition*) provides a more certain means to prevent suspension.

`Dec` is a *system shared noun*. That is, it is always shared with the APL system, and APL can set it. In particular, APL always sets `Dec` so that it is never without a value. Within any verb to which `Dec` is local, APL immediately sets its value to 1. The verb may then contain a statement such as `Dec←0`. However, it is not necessary to set a initial value `Dec←1` because merely by making `Dec` local, you direct APL to set it to 1.

Within a verb whose definition localizes `Dec`, there is *no* interval during which an event could occur before the verb has had time to set `Dec` to 1, since it automatically has that value by virtue of being localized.

Effect of 1 as the Value of `Dec`

As long as the value of `Dec` is 1 at any level of the state indicator, a user-defined verb cannot be suspended *unless* the current line is one for which the *sa* stop-control has previously been set. Thus, unless stop-control has been set, an event must either:

- be successfully trapped
- or*
- cause the active verb to be abandoned, and the event signaled to the environment that invoked it.

Consider the behavior of a verb *foo*, whose definition is as follows:

```

      V z←a foo w
[1]   z←w+a
      V

```

When *a* is 0 but *w* is not, the arguments are outside the domain of +. That is a domain error. How APL responds to that event depends on the value of *Dec*, as follows:

<pre> Dec←0 0 foo 12 domain error foo[1] z←w+a A)si foo[1] </pre>	<pre> Dec←1 0 foo 12 domain error 0 foo 12 A)si </pre>
--	---

When *Dec* is 0 (its default value in a clear workspace), the verb *foo* halts on line 1, and the error report points to the symbol +. But when *Dec* is 1, execution of *foo* is halted. The event is still reported as *domain error*, but is attributed to *foo* rather than to a sentence within it.

To set *Dec* globally to 1 is usually more protection than is needed. Instead, you may set it to 1 only for some critical section of a definition. That can be achieved by a sequence such as the following:

```

[ ] [non-critical work...]
[ ] Dec←1
[ ] critical section
[ ] Dec←0
[ ] [more non-critical work...]

```

Values of *Dec*

Dec is binary: you may set it only to 1 or to 0. In a clear workspace, the default value of *Dec* is 0. If you set it to anything other than an item 1 or 0, APL resets it to 0.

Dec←1 in the SI Stack Prohibits Suspension

Like *Decap*, *Dec* has the important property that APL does not consider only the *visible* (that is, most local) value, but *any* value, at *any* level of the state indicator. As long as *any* *Dec* has the value 1, the *only* untrapped event that can cause execution to be suspended is a stop-control, set prior to the event by *sā*.

To visualize the effects of `Dec` and `trap` at various levels, consider the diagram in Figure 9-1. It assumes that `verb1` invokes `verb2` which invokes `verb3` which invokes `verb4`. Since the state indicator shows the most recently invoked verb at the top, `verb4` is shown at the top and `verb1` at the bottom. An additional row at the bottom shows the global environment before `verb1` was invoked.

The column at the center indicates where `Dec` has been localized and shows the values to which it has been set. The column at the right shows the effective value of `Dec`. The behavior of `Dec` is unlike that of any other name. While the value of `Dec` is 1 at any level of the state indicator (regardless of whether it is explicitly set to 1 or has the value 1 by default), its effective value at all higher levels of the state indicator is 1. Thus the effective value may be controlled by a `Dec` that the higher levels can neither see nor set. (Compare Figure 9-1 with Figure 8-1; the 1 in the `Dec` localized by `verb2` is effective despite being masked by those localized in `verb3` and `verb4`.)

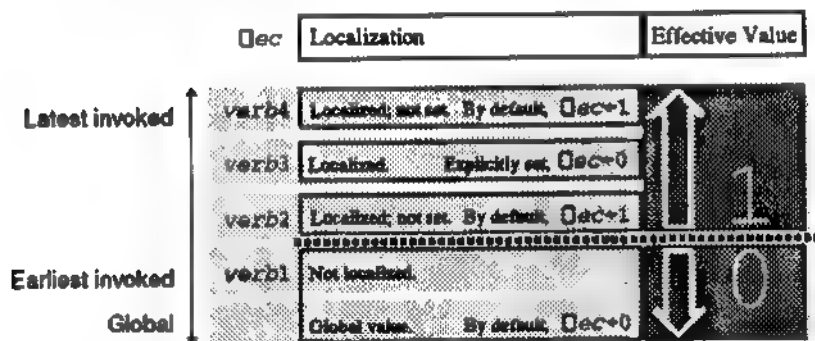

Figure 9-1: Effective value of `Dec` is the maximum `Dec`.

Since `Dec` is localized by `verb2`, no event can cause suspension in it or in `verb3` or `verb4`, regardless of how `verb3` or `verb4` may set their own local values of `Dec`.

Response to an Event When Stop is Prohibited

What happens when a verb that is not allowed to stop does not know how to continue?

During execution of a verb `v` in an environment where the effective value of `Dec` is 1, an event has the following effect:

Stop Control (event 1001)	Halts execution in the usual way.
Weak Interrupt (event 1002)	<p>APL notes the interrupt but postpones acting on it until the effective $\square ec$ becomes 0 (which might not be until it completes execution of the verb that localized the effective $\square ec$). As a consequence, a weak interrupt has its effect on the verb that invoked v rather than on v itself.</p> <p>Although delayed, the weak interrupt has been noted; a second interrupt signal can still upgrade it to a strong interrupt.</p>
Error or Strong Interrupt (except events 1001 or 1002)	Execution of v is halted, and the error that occurred in v is instead signaled to the verb that invoked v .

What Happens When an Event Occurs

When APL detects an event (that is, an error or an interrupt), it does the following:

Notes the event for $\square er$ Eventually, APL records the event in $\square er$. However, this record goes into the $\square er$ visible at the level at which the event is handled. If the event is re-signaled to the next level (because stopping is not permitted at the present level), the note of the event is carried with it, as many times as necessary, until the level at which there is a suspension or the event is finally trapped.

Checks $\square trap$ APL searches the visible (that is, most local) value of $\square trap$ for a trap that covers the event number just encountered. It searches $\square trap$ from top to bottom, left to right. The first trap which covers the event is used.

When the $\square trap$ being searched contains a trap statement that applies to this event, APL carries out the indicated recovery action. If that is sufficient to resume execution, execution resumes and there is no further consideration of $\square trap$ or $\square ec$.

Checks $\square ec$ When no applicable trap is visible, or there is one but its execution does not cause a resumption of execution, APL checks the value of $\square ec$ at every level of the state indicator from the current level down. If $\square ec$ is not 1 at any level, execution halts.

If $\square ec$ anywhere is 1, APL takes the exit procedure described below.

Checks further When no relevant trap has been found but $\square ec$ is everywhere 0, APL digs deeper in its search for an applicable $\square trap$. It examines the next level at which $\square trap$ has been localized. If at the next level it finds an applicable trap that resumes execution, it takes that action. But if it does not find one, it repeats the cycle, considering the next level at which $\square trap$ has been localized, until it reaches the global $\square trap$ value.

■ ■ ■ When at any of the levels checked:

- the event has *not* been handled by a trap
and

- $\square ec$ anywhere in the state indicator has the value 1,

APL abandons execution of the verb at the top of the state indicator and signals the same event to the verb that invoked it (that is, the verb next below it on the state indicator).

This new event starts the examination of trap and environment all over again, possibly cascading further down the state indicator, and possibly reaching a level at which $\square ec$ is no longer 1.

Hint Only when it has checked back through all levels of the state indicator, and at each level has found no applicable trap that resumes execution, *and* has worked down to a level at which $\square ec$ is no longer 1, does APL suspend work with a message describing the event.

Then APL sets $\square ex$ with the event number passed back through the various levels. The event number is that of the original event. However, the event is attributed to the verb in which the event was most recently signaled. When there was a cascade of events because the original event took place at a level where stopping was prohibited, that information is discarded, only the most recent level shows.

Once execution stops, you may edit the definition of the pending or suspended verbs (see Chapter 7, "Verb Formation"), restart or halt the suspended verb, or enter a new sentence for execution (see Chapter 8, "Control of Execution").

Caution: Trapping Interrupts or Prohibiting Suspension

Prohibiting suspensions can make debugging difficult, since it becomes impossible to see where the precipitating event took place. However, it is relatively simple to use no `Dec` in the main body of definitions, and set `Dec` to 1 only in an outer verb which invokes the others.

Since `Dec` is in that case global to the verbs that do the work, if you do not wish users of your application to be able to suspend it, you must prevent them from setting stop controls on your verbs.² You can do that by locking the definitions, or by making their names local to the calling function and reading them from a file during execution (so that they have no global existence in the workspace).

Trapping interrupts is sensitive. Interruption is the means by which a program's user or designer reasserts control when things are going wrong. You may trap interrupts in order to achieve a more graceful recovery, but be aware that a program in which interrupts have been trapped improperly may be impossible to stop.

Caution: After Suspension, `Qtrap` Is Still Active

When you have control at the keyboard, but there is a suspended verb on the state indicator, even though APL did *not* find a trap for the event that caused execution to suspend, `Qtrap` is still there *and may respond to errors in what you enter now*. If you enter a new error and the new error is trapped, the recovery expression may abandon the suspended verb or resume the suspended verb's execution.

When you want to experiment following an error, it is prudent to save the visible `Qtrap` and reset it temporarily to something that causes all events to behave as if no `Qtraps` were present (for example, `Qtrap~'n s'`).

² Editing the definitions (for example, to insert `Dec~0`) would make a difference only if your application had no more than a single level of `Dec` localization, so that the visible `Dec` was the only `Dec`.

10 *APL Component Files*

The component file system provides access to files that contain APL nouns.

Concepts of APL Component Files

Components

An APL file is made up of *components*. The APL file system transfers data between a file and the active workspace one component at a time.

Each component of an APL file is a noun. Like a noun in a workspace, a component may be an array of any rank (item, list, table, higher-dimensional array); its data may be of any type (numeric, character, boxed, or package). A file may contain the definition of a user-defined verb either as its character representation or as the referent of a name in a package.

Each component may be of any size. Moreover, when you replace the noun stored in a particular component, the replacement may also be of any size.

Indexed Access

A component of a file is identified by its *component number*. Component numbers are consecutive positive integers, ranging from the number of the first component up to the number of the last component. Components are numbered in 1-origin, so that the lowest possible component number is component 1.¹

File Size

There is no limit to the total size of a file other than that imposed by the physical limits of the system that contains it.

A common use of files is to partition data into components that may be processed serially, to reduce the amount of data in the workspace at a given moment. In similar fashion, a large application may partition the set of definitions it uses into those required at different phases of the work. A master program reads in the definitions needed for a particular phase, and

¹ The first component is initially component 1. However, if you drop some components from the beginning of a file, those that remain are not renumbered, so the first remaining component will then have a number higher than 1.

then, when they are no longer required, replaces them with those needed for the next phase.

File Reservation

When an APL file is created it is given a file reservation. If the file's size exceeds its reservation, APL will not permit you to append components or to replace existing components with larger ones. APL will accept a change that takes the file past its reservation. You can "resize" a file to set a new limit.

File Primitives

A component file is manipulated by primitives that you can enter at the keyboard or execute from within an APL program. Each of the file primitives is a *system verb*, written with a name whose first character is `⓪`. They are summarized in this chapter and described individually in Chapter 11, "System Nouns and Verbs".

Tying Links a File to the Verbs that Use It

To make use of a file, you must first *tie* it. APL can have several files tied at the same time. The tie verbs `⓪tie` and `⓪stie` pair the name of a file with an arbitrary positive integer called the *tie number*. While the file remains tied, you identify the file *not* by its name but by its tie number. On a single user system, the verbs `⓪tie` and `⓪stie` have the same effect.

Duration of a File Tie

Once you have tied it, a file remains tied until you *erase* it with `⓪erase`, *untie* it with the `⓪untie`, or the session ends.

A file tie is *not* affected by changes to the active workspace; in particular, it is unaffected by such actions as clearing the active workspace or loading a saved workspace.

File Access Controls

Each file has an *access table*. The access table has three columns.

User number (column 1) User numbers are not supported in single user systems and the value 0 should be used to indicate "any user".

Permission code (column 2) A number to indicate which file verbs may be used when tied with the passnumber in column 3.

Passnumber (column 3) An arbitrary integer supplied both when tying the file and as part of the argument of most verbs used with the file. Passnumber 0 is equivalent to "no passnumber."

The access table may provide more than one way for a user to tie a file. For example, a user might be granted "read only" access when tied with passnumber 12345, but "read and replace" access when tied with 7863. The *effective permission* is the one corresponding to the *first* occurrence (scanning from the top) of the passnumber used to tie the file. A task cannot tie the same file in more than one way at one time.

The list of permitted verbs is encoded as an integer, called the *permission code*. Each of the separate permissions is a power of 2. The overall permission code that appears in a file's access table is the sum of the codes for the permitted actions. The number -1 is used to mean "any verb". Figure 10-1 shows the values for the separate permissions.

Access Control Values in Base 2 Base 10 Permissions Granted

0000 0000 0000 0000 0001	1	Read, Size
0000 0000 0000 0000 0010	2	Tie
0000 0000 0000 0000 0100	4	Erase
0000 0000 0000 0000 1000	8	Append
0000 0000 0000 0001 0000	16	Replace
0000 0000 0000 0010 0000	32	Drop
0000 0000 0000 0100 0000	64	Hold
0000 0000 0000 1000 0000	128	Rename
0000 0000 0001 0000 0000	256	Ordac, Ostac
0000 0000 0010 0000 0000	512	Ordci
0000 0000 0100 0000 0000	1024	Oresize
0000 0000 1000 0000 0000	2048	Ofhold
0000 0001 0000 0000 0000	4096	Ordac
0000 0010 0000 0000 0000	8192	Ostac
0000 0100 0000 0000 0000	16384	Oappendr
0000 1000 0000 0000 0000	32768	Osize

-1 Gives unlimited access.

Figure 10-1: Table of file permission codes.

Summary of File Verbs

Full definitions of each of the component file verbs are in the alphabetical list of system nouns and verbs in Chapter 11, "System Nouns and Verbs".

Qappend Append component.

Qappendr Append component and return component number.

Qavail File system availability.

Qcreate Create file.

Qdrop Drop components.

Qerase Erase file.

Qfhold File hold.

Qhold File hold.

Qlib Directory list of files.

Qnames Names of tied files.

Qnums Tie numbers of tied files.

Qrdac Read file access table.

Qrdci Read component information.

Qread Read component.

Qrename Rename file.

Qreplace Replace component.

Qresize Resize file.

Qsize Size of file.

Qstac Set access table.

Qstie Share-tie file.

Qtie Tie file.

Quntie Untie files.

System verbs are primitives without symbols. They are primitive in the sense that they are “built in,” and need no definition. However, unlike the main body of primitives, they have not been assigned symbols. Instead, each has a fixed *distinguished name* that starts with the symbol \square (*quad*) or \square (*quote-quad*), possibly followed by some letters. For example, $\square cr$ returns the *canonical representation* of a user-defined verb. Since you are not permitted to use \square and \square in user-assigned names, these distinguished names are distinct from any names you could give to user-defined objects.

System nouns are names that are always shared with the APL system. You can refer to their values, but so can the system. Like system verbs, the systems nouns have fixed distinguished names. The system attaches special significance to each. For example, $\square io$ establishes the *index origin* (which may be 1 or 0), and $\square pw$ establishes the *page width* for displays.

Certain system names report the current value of system statistics. For example, $\square ts$ contains the *timestamp*, reporting the date and time, and $\square ai$ contains *accounting information* regarding the current user. For most purposes, it is moot whether these names denote nouns, or verbs that take no argument. This manual describes them all as nouns. Figure 11-1 indicates which you can set.

System Noun	You Set	
Qal	—	Accounting information
Qav	—	Atomic vector
Qct	Yes	Comparison tolerance
Qec	Yes	Environment condition
Qer	Yes	Event report
Qfc	Yes	Format control
Qio	Yes	Index origin
Qlx	Yes	Latent expression
Qlc	—	Line counter
Qnames	—	Names of tied files
Qnums	—	Numbers of tied files
Qpp	Yes	Printing precision
Qps	Yes	Position and spacing
Qpw	Yes	Page width
Qrl	Yes	Random link
Qsc	Yes	State change
Qts	—	Timestamp
Qtrap	Yes	Trap expressions
Qul	—	User load
Qwa	—	Work area

Figure 11-1: System nouns, indicating which you can set.

Results of System Verbs

A few of the system verbs return no result (and do their work as side effects).

Alphabetical List of System Names

⌊ai

Accounting Information

System noun **⌊ai** provides accounting information. This is not implemented and returns 990.

⌊append

Append Noun to Tied File

Noun **⌊append to** [, **pn**]

Dyad **⌊append** writes **Noun** as a new component appended at the end of the file whose tie number is **tn**.

Noun is any noun to be appended as a new component at the end of the file. **tn** is the tie number to which the file is tied, followed by a passnumber **pn** (if you used a passnumber when you tied the file).

Effect: Provided that the number of bytes the file already occupies does not exceed the file's size limit, a new component is appended. That component contains the noun **a** together with its description, which indicates type, rank, and shape.

File permission: 0.

Result: None.

⌊appendr

Append Noun to Tied File with Result

Noun **⌊appendr to** [, **pn**]

Dyad **⌊appendr** writes **Noun** as a new component appended at the end of the file whose tie number is **tn**.

File permission: 16384.

Result: An integer item whose value is the component number of the new component.

⎕arbin

Arbitrary Input with Arbitrary Output

⎕arbout

Arbitrary Output

Monads **⎕arbin** and **⎕arbout** have different definitions on different systems and are not documented here. A special use of **⎕arbout** in input is the same on all systems and is documented in section "Discarding the Prompt" in chapter Chapter 3, "Nouns and Pronouns".

⎕av

Atomic Vector

The noun **⎕av** is a list of all possible character values in the APL system, in numeric order of their internal encoding, from hex 00 to hex FF (decimal 0 to 255).

A common use of **⎕av** is to provide a reference for translating characters to their numeric equivalents, for example

⎕av10

or to translate from one character encoding to another, by an expression such as

NewA1f[⎕av10d]

To avoid loss of information, **NewA1f** should be a permutation of **⎕av**; that is, a list in which each of the 256 possible characters occurs exactly once.

⎕avail

File System Availability

Monad **⎕avail** reports whether the APL component file system is available for use. The only acceptable argument is an empty list.

Result: The Boolean item 1 if the file system is available for use. Otherwise, a Boolean item 0.

⎕bounce

Terminate Task

Monad **⎕bounce** takes any scalar argument and terminates APL.

⊞cr**Canonical Representation**

Monad **⊞cr** returns the representation of the most local definition of the verb named in its argument. The result is a character table containing the definition of the verb in *canonical* form; that is, without leading or trailing del symbols (⌈) or bracketed line numbers. Each line (including the header) is flush-left. Lines shorter than the longest are right-padded with blanks.

When the argument contains a well-formed name but the visible referent of the name is not an unlocked user-defined verb, the result is an empty table with shape 0 0.

⊞create**Create a File**

fn ⊞create *tn*

Dyad **⊞create** creates a new file with name *fn*, and share-ties it with *tn*. *tn* must be a positive integer less than 2³¹ that is not already in use as a tie number.

For example:

'michigan' ⊞create tfn

fn is a character list containing a file name that is both valid (that is, well formed) and available (that is, not already in use). The rules for valid names may vary from system to system and are documented in online [documentation](#).

Effect: A new file with no components is created and share-tied to the tie number in the right argument.

File permission: None.

Result: None.

Oct

Comparison Tolerance

The system noun `Oct` establishes the maximum relative difference allowed between two numbers if they are to be considered equal. Comparison tolerance permits the interpreter to ignore small differences between numbers likely to arise from inexact internal representations that are inherent in computer arithmetic on numbers that are not integers.

Some numbers are inherently incapable of exact representation (for example, π , e , $\sqrt{2}$). Other inexact representations arise because input and display are normally in base 10, but internal representations are in base 16. For example, the representation of 0.1 in binary is an endless sequence of binary digits, even though it is finite (and short) in base 10. Yet others arise from rounding errors, when numbers that do in principle have finite representations must be truncated to fit within the system's word size. Tolerant comparison permits reasonable identities to work even when the system is incapable of representing them properly. Thus, the expression

$$1 = 3 \div 3$$

is reported as true, despite the fact that 3 times the reciprocal of 3 does not really produce an exact 1.

In a clear workspace, the default value for `Oct` is $1.41969769e^{-14}$ (computed as 1023×16^{-14}). You may assign the visible `Oct` to be any numeric item not less than 0, and less than 16^{-4} . Before you set `Oct` to zero, it may be rewarding to consider the effects of intolerant comparison in the example shown in Figure 11-2.

A way to get exact comparison without setting `Oct` to zero is by comparison with zero. Instead of $x=y$ with `Oct` $\neq 0$, use $0=x-y$.

Verbs Affected by Oct

The visible value of `Oct` is part of the definition of the following verbs when an argument is represented internally in floating point or complex form.¹

Dyads: `|` `^` `∨` `∩` `<` `≤` `=` `≠` `≥` `>` `≡`

Monads: `⌊` `⌈` `≠`

`Oct` is a relative comparison tolerance. When two numbers are compared and at least one of them is a floating-point number, their relative difference

¹ The maximum permitted value of `Oct` is chosen so that `Oct` could never affect the outcome of any of these verbs when applied to the arguments that could be internally represented as integers.

(which depends on their magnitudes) is compared against Δct . Two numbers are considered equal if their relative difference is less than or equal to Δct . That is, α and ω are judged equal when:

$$(|\alpha - \omega| \leq \Delta ct \times (|\alpha| + |\omega|))$$

When one of the arguments (say, ω) is 0 but the other is not, that inequality reduces to:

$$(|\alpha| \leq \Delta ct \times |\alpha|)$$

Since Δct must be (much) less than 1, the inequality can never be satisfied. Thus the value of Δct can never affect a comparison with 0.

When Δct is 0, all comparisons are exact. The judgment "not equal" may be produced by bits that would otherwise be considered insignificant.

Figure 11-2 shows how the results of some simple expressions depend upon the value of Δct .

$eps = 1e^{-14}$	a	0	0	1	1
	b	$0 + eps$	$0 - eps$	$1 + eps$	$1 - eps$
$\Delta ct = 0$	$ b$	0	1	1	0
$\Delta ct = 10 \times eps$	$ b$	0	0	1	1
$\Delta ct = 0$	$ b$	1	0	2	1
$\Delta ct = 10 \times eps$	$ b$	0	0	1	1
$\Delta ct = 0$	$a = b$	0	0	0	0
$\Delta ct = 10 \times eps$	$a = b$	0	0	1	1
$\Delta ct = 0$	$a < b$	1	0	1	0
$\Delta ct = 10 \times eps$	$a < b$	1	0	0	0
$\Delta ct = 0$	$a \leq b$	5	5	5	5
$\Delta ct = 10 \times eps$	$a \leq b$	5	5	3	3
$\Delta ct = 0$	$a \leq b$	0	0	0	0
$\Delta ct = 10 \times eps$	$a \leq b$	0	0	1	1

Figure 11-2: Tolerant and intolerant comparisons.

The following illustrate the effects of `⌈ct` in a few simple examples:

```
⌈ct
1.419697693e-14

⌈a←a⊙6
6

a←6
1

⌈a
6

⌈ct←0
a←6
0

⌈a
7

a←6
-2.220446049e-16
```

`⌈dl`

Delay Execution

Monad `⌈dl` delays execution of the statement in which it appears. ω is a numeric item, specifying the duration of the desired pause in seconds. The result is a numeric item, the actual delay in seconds.

When the delay completes normally, the result is not less than ω . The actual delay (reported as the result) may be slightly more than requested. For example:

```
⌈dl 10
10.033      (Appears about 10 seconds after pressing
             Enter on the line above.)
```

Behavior of Delay When Interrupted

The delay produced by `⌈dl` can be cut short by a weak interrupt. As usual, a weak interrupt halts execution at completion of the end of the line being executed. The weak interrupt causes `⌈dl` to return its result without further waiting. When the system has completed execution of the entire

line, execution halts before starting a new line. (A weak interrupt on a line containing multiple instances of `⌋dl` cuts short all those that have not yet delayed.)

Since a weak interrupt causes an immediate return from `⌋dl`, a definition for strong interrupt does not arise.

⌋drop

Drop File Components

Monad `⌋drop` *w* drops components from the beginning or end of a tied file. The argument is:

`⌋drop m,n [,pn]`

m The number of a tied file.

n Number of consecutive components to drop. A positive number counts from the beginning, a negative number from the end of the file.

pn The passnumber, if the file was tied with a passnumber.

Effect: The indicated number of components is dropped from the file. You can drop a block of consecutive components either from the beginning or from the end of a file. That reduces the range of valid component numbers. Suppose a file has 100 components, numbered from 1 to 100. If you drop the last 10, it will then have 90 components, with numbers running from 1 to 90. But if you drop the first 10, it will have 90 components numbered from 11 to 100. Dropping components from a file does *not* alter the numbers by which you refer to the components that remain.

If you attempt to drop more components than exist, the system rejects the expression with the message *file index error*.

File permission: 32.

Result: None.

□ec

Environment Condition

The system noun □ec is part of the event trapping apparatus. Its value is restricted to a Boolean item. When its value is 1 *at any level of the state indicator*, an *untrapped* error in a defined verb causes an exit from the verb (whereas otherwise execution would halt). However, a stop control² still halts execution in the usual way.

As illustrated in the right side of Figure 11-3, when □ec is set to 1, upon encountering an error, APL exits from *foo* and attributes the error to the verb *foo* as a whole, rather than to a specific statement within it.

Example with □ec set to 0:

```

V foo; □ec
[1] □ec←0
[2] 2+ * Error
V

      foo
syntax error
foo[2] 2+ * Error
      A

```

Example with □ec set to 1, or localized but not set:

```

V foo; □ec
[1] □ec←1 *Can omit this
[2] 2+ * Error
V

      foo
syntax error
      foo
      A

```

Figure 11-3: Behavior of errors depending on □ec setting.

□ec is a *system shared noun*. That is, it is shared with the APL system, and the system may set its value. In particular, whenever APL starts execution of a verb whose definition localizes the name □ec, APL immediately sets □ec to 1. As a consequence, when □ec appears in a verb's header, there is no way to interrupt it in a way that leaves it suspended until the verb itself has set □ec to 0.

When □ec has the value 1 (either because it has been explicitly set, or because APL has set it because it is localized), any verb invoked within the verb to which □ec is local is also affected. Moreover, this extends to *all* verbs that may be invoked, regardless of level, and regardless of whether they localize □ec. Once an outer verb (that is, one that appears lower in the state indicator) has localized □ec, a verb can halt only when:

- The visible value of □ec and *also* the value of □ec at *all* levels of the state indicator are 0

² For a verb *v*, the expression *zAV←n* sets stops on the lines of *v* whose line numbers are members of *n*.

or

- A stop control is set for one of the verb's lines and event 1001 (*stop*) is not trapped.

See also Chapter 9, "Event Handling".

Der Event Report

This noun is set by the interpreter whenever an error, interrupt, or other such event occurs during the execution of a program. You (or the recovery expression contained in *Dtrap*) may then examine *Der*, perhaps just to display it, or to decide on remedial action.

When *Der* is localized, the *Der* that is set is the one viable at the level at which the event is handled. When the event is trapped and the recovery expression uses action *c* to cut back the stack, or when *Dec* is 1 so that a halt is not permitted, the error report appears not in *Der* of the level at which the event originally occurred (which may no longer exist), but at the level of the effective trap (when the event is trapped), or the level at which execution halts (when the event is not trapped).

In general, *Der* is a table with three rows. It has a fourth row when the event is 6, *value error*, and the event has been trapped with action 1 (*immediate*). The rows contain:

- Der*[1;4] The event number, in four characters, right justified. Figure 11-4 contains a list of the event numbers that are currently generated by APL.
- 5+*Der*[1;] The event title. For events signaled by APL, this is the standard name associated with the event (see Chapter 9, "Event Handling"), as modified by the current setting of *)nlc*. An event signaled by *Signal* may have its own event title, specified by the left argument of *Signal*.
- Der*[2;] The sentence being executed when the event occurred.
- Der*[3;] Caret pointing to the part of the line being executed when the event occurred.
- Der*[4;] The name that lacks a value (when event 6 has been trapped with action 1).

When the workspace is so full that there is insufficient room for an appropriate *Der*, APL makes *Der* a four-element list containing only the character representation of the event number.

**** Not reported in Qer.

Figure 11-4: Event numbers.

Qerase

Erase a Tied File

fn Qerase *tn* [, *pn*]

Dyad Qerase erases the file tied to *tn* whose name is *fn*, with optional passnumber *pn*.

For example, if file *datafile* was tied to *dfn*, it is erased by the expression:

`'datafile' Qerase dfn`

The left argument is redundant: all this information is available from the tie number. However, the system requires you to provide both forms of identification to make it less likely that you will inadvertently erase the wrong file.

Effect: The file ceases to exist. The number formerly tying it is again free for use. The file's name disappears from the result of Qnames, Qnames, and Qlib. The APL system marks the space the file occupied as available for other use.

File Permission: 4.

Result: None.

Qex

Expunge Objects

Monad Qex expunges (that is, erases) from the active workspace the most local referent of each of the names in its argument. *w* may contain zero or more names, arranged as a table with one name per row, or as a character list or item when there is only one name.

The result is a Boolean list, with one element for each name in the argument. Each element of the result contains:

- 1 When the corresponding name is now free (either because it had no referent or because its former referent has been erased).
- 0 When the corresponding name is not free (either because it has a referent that cannot be erased, or because it is not a well-formed name).

Dex does not erase a name whose referent is a label or a system noun or verb. A verb that is executing, pendent, suspended, or waiting cannot be erased.

If Qex produces a *ws full* or *domain error*, nothing has been erased.

□fc

Format Control

The system noun □fc acts as a global argument to dyad v with a character left argument (*format by example*). It specifies how v deals with certain cases. □fc is a six-item character list. The following list shows the value assigned in a clear workspace, and the significance each item has in formatting:

- fc[1] • Decimal point. Character to separate the integer part from the fractional part of a fraction. This character replaces . where it appears in α as a decimal point.
- fc[2] • Grouping separator. This character replaces , where it appears in α with digits on both sides.
- fc[3] * Fill to represent insignificant digits at positions marked in α by an 8.
- fc[4] * Character to fill an overflow field (one too small to contain the representation of a number in ω). When □fc[4] is the character 0, an overflow in any field causes APL to reject the entire expression αvω as a domain error.
- fc[5] - Marker for blank. Where this character appears in α as a controlled character (that is, embedded within the positions devoted to the number representation), the result contains a blank.
- fc[6] - Proposed as character in the result to indicate a negative value. (Not implemented.)

For more information on v, see Chapter 5, "Verbs".

□fd

Verb Definition

Dyad □fd provides services for conversion between a verb and its character representation. α is a numeric item and selects one of the services described below. Its value must be a member of the set 1 2 3 6 7.

- 1 □fd ω *List representation.* ω is the name of a user-defined verb, as a character list. The result is a character list (including *new-line* characters at the line boundaries) showing the definition the way it looks when displayed by the V-editor: with line numbers enclosed in brackets, and a leading and closing v. When α is not the name of a verb, or has a locked definition, the result is an empty list.

2 `⌈fd ω` *Table representation.* $ω$ is the name of a user-defined verb as a character list. The result is a character table containing the *canonical representation* of the verb's definition, with one row for each line of the definition. The lines are shown the way they look when displayed by `⌈cr`: flush-left, without line numbers, and without the opening and closing `▽`. When $α$ is not the name of a verb, or has a locked definition, the result is an empty table.

3 `⌈fd ω` *Fix a verb from its representation.* $ω$ is the character representation of a user-defined verb. It may be in either the table form returned by `⌈cr` or 2 `⌈fd`, or the list form returned by 1 `⌈fd`, with successive lines separated by a newline character, with or without line numbers, with or without opening and closing `▽`. Blank lines are permitted within the representation.

Side effect: The verb defined by $ω$ is *fixed* (that is, materialized in the workspace) in the same manner as `⌈fx`. A definition can be fixed provided the name shown in $ω$ is available: that is, has no visible use, or its visible referent is to a verb (in which case the new definition replaces the old).

When the name of the verb to be fixed has been localized in some verb that is currently on the state indicator stack, the newly defined verb is local to that verb. It ceases to exist when the verb to which its name is local completes execution.

Result: The name of the verb thus fixed. When for any reason the definition cannot be carried out, the result is a two-element numeric list whose first element is a diagnostic code and second is an index in the argument of the error. The diagnostic codes are:

- 1 Workspace full
- 2 Definition error
- 3 Character error
- 4 Symbol table full

6 `⌈fd ω` *Expunge names.* $ω$ is a *namelist*, that is, either a list with successive names separated by blanks, or a table with one name per row. Each of the names in $ω$ is *frees*: that is, its visible referent is expunged so that the name is free for other uses. The result is a table containing those names that were *not* freed (because their referents cannot be expunged or because they were not well formed). Thus when 6 `⌈fd` is successful, the result is an empty table.

7 `⊞fd ω` *Lock verbs.* *ω* is a *namelist* (as defined above). Each of the verbs named in *ω* is locked. The result is a table containing those names that were *not* locked (because their visible referents were not verbs). Thus when 7 `⊞fd` is successful, the result is an empty table.

`⊞fhold`

Hold Tied Files

Coordinates access to shared files by different APL tasks. Shared component files are not supported and `⊞fhold` has no effect.

`⊞fi`

Input Format Conversion

Monad `⊞fi` returns the numeric values of the fields in a character list. It assumes that within *ω* fields are delimited by blanks.

The result is a numeric list containing the value of each well-formed numeric field, and 0 for each other field.

```
⊞fi '666 -1.20 -5.5 .1 314159e-5 five'
666 -1.2 0 0.1 3.14159 0
```

The value *-5.5* is invalid because it contains a minus sign — instead of a negative sign `-`.

`⊞fi` accepts any of the forms that may appear in default system output (or in the result of monad `v`). That includes integers, decimal fractions, *e*-formats, complex numbers, and numbers preceded by `-` to indicate negative values. Those are the only forms `⊞fi` recognizes; in particular, it does not consider well-formed a field that contains a currency symbol or embedded commas, or that is enclosed in parentheses, and returns 0 for each such field.

```
⊞fi 'Take 3 spoons of 150 proof rum'
0 3 0 0 150 0 0
```

```
⊞fi 'Sent $3.00 for 6 kilos on 07/4/1'
0 0 0 6 0 0 0
```

To permit `⊞fi` to convert some common but otherwise unacceptable formats, techniques such as the following may be useful:

```

ext←' 0123456789e.-'
int←' 0123456789e. --*'
⊞fi int[ext] ,25 -6.25 8,9,10]
0.25 -6.25 8 9 10

```

Use of `⊞fi` with `⊞vi`

Since `⊞vi` returns a Boolean result indicating which fields were well formed, the expression

$$(\odot vi \omega) / \odot fi \omega$$

returns only the values of the well-formed numbers.

`⊞fm`

Function Monitor

`⊞fm` collects and reports measures of frequency of use, CPU time and elapsed time during the execution of user-defined verbs.

CPU and elapsed time results on PC systems are erratic because of the very low resolution timer and can be misleading.

Dyad `⊞fm`

Dyad $\alpha \odot fm \omega$ sets or reports monitoring. ω is a character array of names, each name in a 1-cell of ω (that is, arranged along the last axis). Commonly, ω is a table with one name per row.

α is a numeric item indicating the data to be collected or reported. It applies to all the verbs named in ω . The sign of α indicates whether you are establishing monitoring or reporting data already collected:

- α *non-negative* Establishes which data should be collected during future executions of the affected verbs.
- α *negative* Establishes which topics should be reported from the data already collected.

The topic (collected or reported) is represented by the sum of the codes for the various possible topics. Since each code is a power of 2, each topic can be enabled or reported independently of the others.

`⊞fm` acts on the visible (most local) definition of each verb. In case of an error during the execution of `⊞fm`, the state of the workspace remains unchanged.

Turning on any form of monitoring for a verb turns off any previous monitor setting for that verb. Turning on any monitoring other than *summary* automatically generates summary monitoring.

The numeric codes for the various monitoring reports are as follows:

- | | |
|-----------|---|
| 0 | <i>No monitoring.</i> When α is zero, this (a) discontinues data collection, and (b) discards data from previous monitoring and frees the space used for its collection. |
| 1 2*0 | <i>Summary monitoring.</i> Records the monitoring information for the topics associated with codes 2 through 128 for the verb as a whole, without line-by-line breakdown. |
| 2 2*1 | <i>Execution count.</i> Records the number of times each line was executed. |
| 4 2*2 | <i>CPU/own.</i> Records total CPU time on each line, but excluding user-defined verbs that the line invokes. |
| 8 2*3 | <i>Elapsed/own.</i> Records total elapsed time on each line, but excluding user-defined verbs that the line invokes. |
| 16 2*4 | <i>CPU/total.</i> Records total CPU time on each line, including user-defined verbs that the line invokes. |
| 32 2*5 | <i>Elapsed/total.</i> Records total elapsed time on each line, including user-defined verbs that the line invokes. |
| 64 2*6 | <i>CPU/non-monitored.</i> Records CPU time for user-defined verbs that the line invokes and are not themselves monitored. |
| 128 2*7 | <i>Elapsed/non-monitored.</i> Records elapsed time in those user-defined verbs that the line invokes but are not themselves monitored. |

The result of dyad \square/ω is an array with a cell for each name in ω (that is, its frame-shape is $\overline{1+\rho\omega}$). The cells are different, depending whether α is 0, positive, or negative, as follows:

α is zero A result cell is an item, reporting the former level of monitoring for each name in ω .

α is positive A result cell is an item, reporting the new monitoring status for each name. When the request to set monitoring is successful, each item in the result has the same value as α . When the system is unable to establish the monitoring requested (for example, because a name

in ω does not refer to a visible user-defined verb), the corresponding element of the result is 0.

α is $\neg 1$ A result cell is a seven-item list. The items within that list are the summary values for each of the reports corresponding to codes 2+1 2 3 4 5 6 7.

α is even and negative Each result cell is a table, containing a line-by-line report, with a row for each line of the verb. (For this reason, ω may ask for a report on more than one verb if and only if the verbs have the same number of lines. A request for reports on verbs with different numbers of lines is rejected as a *length error*.)

Each result cell has a column for each of the topics requested in α . A request for a report on a topic for which monitoring has not been enabled is rejected as a *domain error*.

The values reported both for CPU time and elapsed time are in seconds.

Monad $\square fm$

ω is a table of names in the same manner as for $\alpha \square fm \omega$.

The result frame has shape $\neg 1 + \rho \omega$. Each cell is a numeric item indicating the monitoring status of a name, encoded in the same way as the left argument of dyad $\square fm$.

Storage Allocated to Monitoring Data

Turning on the monitor for a verb (by $\alpha \square fm \omega$ with a positive left argument) causes the interpreter to allocate additional space in the verb definition, in order to accumulate the requested data. The additional space is included in the result of $\delta \square ws$.

When you save a workspace, a verb's monitoring data is saved with it, and is loaded when the workspace is subsequently loaded, so that monitoring may span *save* and *load*.

However, copying, editing, fixing, or defining a definition⁸ turns off monitoring and discards the space formerly allocated for data collection. When you pack the definition of a verb, monitoring is similarly discarded from the definition in the package. (The original verb is not changed; only the copy created inside the package.)

⁸That is, *copy*, *redefine*, *fix* or *3 Dfd*, *update* or *updateL*.

You may set monitoring on a verb that is pendent or suspended. Monitoring takes effect at once, but (naturally) lacks data on the portion already executed.

When an event is trapped, the cost of executing the recovery expression is charged to the line that was active when the event was trapped.

You request monitoring of a verb whose definition is locked, but only with a left argument of `1` (summary). If you lock the definition of a verb for which monitoring was already in effect, monitoring is thereby turned off (but you may then request summary monitoring).

Monitoring a Recursive Definition

You can monitor a recursive or re-invoked definition. The total CPU and elapsed time spent on lines including invoked verbs is equal to the time spent on the root verb. Suppose you have a verb *foo* that calls *foo* that in turn calls *foo*. You can think of that as though the invoked versions are different verbs: as though *foo* calls *foo2* that calls *foo3*, and you are only recording data for *foo*.

When there is *no* recursion, the column for *Total CPU*, including invoked verbs, is equal to the sum of `16` `⌊fm` `ω`. When there is recursion, the sum of `16` `⌊fm` `ω` is greater than the actual CPU time consumed by the verb.

Similarly, when there is *no* recursion, the column indicating total elapsed seconds, including invoked verbs, is equal to the sum of `32` `⌊fm` `ω`. When there is recursion, the sum of `32` `⌊fm` `ω` is greater than the actual elapsed time consumed by the verb.

□fmt**Format Output**

Dyad □fmt formats character and numeric data into a character table. The conventions for the left argument of □fmt resemble certain of those used in Fortran or Cobol.

Format Phrases

ω is a character list divided into *format phrases* separated by commas. See Figure 11-5 for a summary of format phrases. For example, the following contains three phrases:

```
f>16,f8.2,g< 999.99>1
```

Each format phrase governs the appearance of a column of *ω*. The number of phrases need not match the number of columns in *ω*; the phrases are repeated cyclically as needed.

Each phrase has a *type*, indicated by a letter,¹ such as the letters *i*, *f*, or *g* in the preceding example.

A *constant* field is reproduced in the output but does not correspond to any column of the data. A constant phrase is enclosed by the characters <> (or also by certain other characters), thus:

```
ff>1<Part: >,16,< Cost: >,f8.21
```

A *tab* phrase does not itself control a field of data, but controls the position in the result at which the next field starts, specified either as a *relative* distance forward or back from the end of the previous field, or as an *absolute* location in the result.

¹The control letters are all from the first alphabet.

<i>n</i>		<i>a</i>	<i>w</i>	<i>Character data.</i> Print each character in a field <i>w</i> positions wide. (Note that when <i>w</i> >1, this inserts blanks between adjacent letters.)
<i>n</i>	<i>q</i>	<i>e</i>	<i>w.d</i>	<i>Exponential fraction.</i> Print in a field <i>w</i> positions wide, with <i>d</i> significant digits.
<i>n</i>	<i>q</i>	<i>f</i>	<i>w.d</i>	<i>Fixed-point fraction.</i> Print in a field <i>w</i> positions wide with <i>d</i> decimal digits. Trailing zeros always print.
<i>n</i>	<i>q</i>	<i>i</i>	<i>w</i>	<i>Integer.</i> Leading zeros are represented by blanks unless the <i>z</i> qualifier is used.
<i>n</i>		<i>x</i>	<i>p</i>	<i>Relative reposition ("tab").</i> Start the next field at the position displaced <i>p</i> positions from the end of the preceding field. The displacement may be negative, in which case the next field may overwrite earlier ones.
<i>n</i>		<i>c</i>	<i>p</i>	<i>Absolute reposition ("tab").</i> Start the next field at position <i>p</i> (possibly over-writing preceding fields).
			<i><text></i>	<i>Constant.</i> Insert <i>text</i> in every row of the result.
<i>n</i>	<i>q</i>	<i>g</i>	<i><text></i>	<i>Picture.</i> Insert the digits that represent the value (rounded to the nearest integer) into the "picture" text. Build the result as follows: Copy <i>text</i> to the field. Then overlay the successive digits of the number's representation. Place the digits at the positions marked in the picture by 9 or z, starting with the low-order digit in the right-most 9 or z. In positions marked z, represent leading or trailing zeros by blanks. Where other text characters are embedded between digits used in the result, keep them. Overlay right decorators to the right of the right-most digit used in the result, and left decorators to the left of the left-most digit used in the result.
<i>n</i>	<i>q</i>			<p>Key:</p> <p>Number of repetitions (optional).</p> <p>Qualifier (see Figure 11-6).</p> <p><i>w</i> Field width.</p> <p><i>d</i> Number of decimal digits (<i>f</i> format); number of significant digits (<i>e</i> format).</p> <p><i>p</i> Number of positions to displace next field.</p>

Figure 11-5: Summary of *fmt* format phrases.

Repetition Factors

A phrase or group of phrases may be preceded by a repetition factor. For example,

```
g←'216,3f8.2,g< 999.99>'
```

indicates that the first phrase (16) is to be used for two columns, the next (f8.2) for three columns, and the last (g< 999.99>) for one.

The repetition factor can apply to a set of consecutive phrases enclosed in parentheses. For example,

```
g←'2(16,3f8.2),g< 999.99>'
```

indicates that the sequence of one column formatted by 16 and three columns formatted by f8.2 is to be repeated twice.

Type and Shape of the Right Argument of $\square fmc$

ω is a numeric array or character array of rank no greater than 2, or list of one or more boxes containing such arrays. When ω is a list or item, it is treated as if it were the one-column table $\gamma\omega$.

When ω is formed as a succession of boxes, each is disclosed, treated as a table, and its successive columns formatted in order from left to right. Columns need not have the same height; short columns in the result are padded with blank rows at the bottom to match the length of the highest.

Shape of the Result of $\square fmc$

The result returned by $\square fmc$ is always a character table. The number of rows is sufficient to accommodate the tallest column in ω .

In the result, successive bands of adjacent columns form *fields* corresponding to the phrases in the left argument α . Each field has the width specified by the corresponding phrase in α . There are no additional columns between fields, so the visual separation of fields in the displayed result is produced either by constant phrases in α , or by specifying formats that are wider than needed to represent the data.

Qualifiers and Decorators

Within each format phrase, to the left of the letter that identifies its type, you may insert various qualifiers or decorators. A *qualifier* (See Figure 11-6) provides additional rules, for example "insert commas between triplets of digits" or "leave this field entirely blank when the value being represented is zero."

A *decorator* (See Figure 11-7) is a piece of text attached to the representation of a number, usually to indicate its sign. Decorators precede the format phrase with which they are associated. When used, decoration text appears to the right of the right-most digit used in the representation, or to the left of the left-most. For example, to enclose negative numbers in parentheses, you need to include in the format phrase the decorators *m* (the left text of a negative number) and *n* (the right text of a negative number, thus:

```
'm(>n<)>f8.2' ⌈fmt 123.45
(123.45)
```

To preserve right-alignment, when you include decorators that appear to the right, you need to specify equal-length decorators for negative and non-negative numbers, thus:

```
'm(>n<)>p< >q< >f8.2' ⌈fmt 123.45 123.45
123.45
(123.45)
```

Alternatively, you may exploit decorators of different size to give different alignment to negative and non-negative values:

```
'm<->q< >f16.2' ⌈fmt 1 1 1 1 × 123.45
123.45
-123.45
123.45
-123.45
```

The background decorator *r* first fills the field by repeating as necessary the character(s) specified, and then overwrites the field with the digits of the representation and the sign decorators. The effect is to leave the background text visible only in the positions unused by the representation. This is commonly used for "check protection," as follows:

```
'r<$*****>f12.2' ⌈fmt 12345.67 5.67
$**12345.67
$*****5.67
```

- b Blank.** Make the entire field blank when the value is zero.
- c Commas.** Insert commas between successive triplets of digits. (May not be used with *g* format.)
- en Scale.** Scale the result by displaying a value 10^e times the value in *w*.
- l Left justify.** Left justify the representation within its field. (May not be used with *g* format.)
- z Zeros.** Print leading zeros or trailing zeros. (NB: in *g* format, *z* within the picture makes leading or trailing zeros blank.)

Figure 11-6: Summary of `□fmt` qualifiers.

- m<text>** *Negative/Left.* Insert *text* to the left of the representation of a negative value.
- n<text>** *Negative/Right.* Insert *text* to the right of the representation of a negative value.
- p<text>** *Positive/Left.* Insert *text* to the left of the representation of a non-negative value.
- q<text>** *Positive/Right.* Insert *text* to the right of the representation of a non-negative value.
- r<text>** *Background.* First fill the field by cyclically repeating *text* across it. Then overwrite the digits and decorators needed to represent the value. Leave the background text visible at positions that are not used for digits, sign, or decorators.
- s<text>** *Symbol substitution.* In each pair of characters within *text*, the first indicates a character used by default and the second the desired substitute. For example, *s<, .,>* displays blank where `□fmt` would otherwise put comma, and comma where `□fmt` would otherwise put dot.

```

□fx

Fix a Definition

Monad □fx *fixes* (that is, makes available for execution) a user-defined verb from the characters of its *canonical representation*.

ω is a character table containing the verb's definition in the form produced by □cx. Each row of the table represents a line of the definition, without leading or closing \vee and without line numbers.

Side effect: The verb defined by ω is *fixed* (that is, materialized in the workspace). A definition can be fixed provided the name shown in ω is available; that is, has no visible use, or its visible referent is to a verb (in which case the new definition replaces the old).

Result: The name of the verb thus fixed. When for any reason the definition cannot be carried out, the result is a numeric item identifying the line number⁵ that contains the error. (Note that this is the same as an index into the rows of ω when □io=0. In 1-origin, line 1 of the proposed verb is located on row 2 of ω , since the first row of ω is devoted to the header.) The result may indicate a row 1 greater than the index of the last row. That happens when ω is empty, or the error is detected after the last row ω has been processed.

When the name of the verb to be fixed has been localized, the newly defined verb is local. It ceases to exist when the verb to which it is local completes execution.

3 □fd provides similar capabilities.

□hold

Hold Tied Files

Coordinates access to shared files by different APL tasks. Shared component files are not supported and □hold has no effect.

⁵The return code from □fx differs from that returned by 3 □fd, which reports the character index into its list argument rather than the line number.

$\square io$

Index Origin

The noun $\square io$ establishes the index origin used by several APL primitives. You may set $\square io$, but the only acceptable values are an item 1 or 0. In a clear workspace, $\square io$ is initially set to 1.

When generating or using index values, APL assumes that they start with $\square io$. Compare the effects produced by leaving $\square io$ at its default value, or setting it to the optional value 0:

$\vdash \square io \leftarrow 1$	$\vdash \square io \leftarrow 0$
1	0
15	15
1 2 3 4 5	0 1 2 3 4
$\vdash x \leftarrow 5 + 15$	$\vdash x \leftarrow 5 + 15$
6 7 8 9 10	5 6 7 8 9
$x[3]$	$x[3]$
8	8
$x[5]$	$x[5]$
10	index error
	$x[5]$
	^
$x[0]$	$x[0]$
index error	5
$x[0]$	
^	
373	373
3 1 2	2 0 1
$v \leftarrow 6 \ 23 \ 11 \ 4 \ ^{-}6$	$v \leftarrow 6 \ 23 \ 11 \ 4 \ ^{-}6$
$\uparrow v$	$\uparrow v$
5 4 1 3 2	4 3 0 2 1
$x_{\square io}[0.5] \ v$	$x_{\square io}[0.5] \ v$
6 7 8 9 10	5 6
6 23 11 4 ^{-}6	6 23
	7 11
	8 4
	9 ^{-}6

Verbs Affected by `⌈io`

The value of `⌈io` is used in connection with:

- 1 Both monad (to generate consecutive integers) and dyad (to return the indexes of ω in α).
- 7 Both monad (roll) and dyad (deal) to generate random integers.
- ⋈ ▽ Both monad (numeric) and dyad (character) grade up and grade down.
- ⌊ Left argument of transpose.
- [...] Selection by indexing. Indexing to select the axis of application of ϕ \bullet \cdot $/$ \backslash .

`⌈lc`

Line Counter

For each active user-defined verb, the system noun `⌈lc` shows the number of the line on which APL is currently working or (when execution is halted) is next to be executed when work resumes.

For example, if at the moment APL is working on line 3 of verb *report* and *report* was invoked by line 5 of *analyze*, the value of `⌈lc` is 3 5.

If you signal a *weak interrupt* while line 3 is active, APL completes execution of the line and halts. The value of `⌈lc` is then 4 5. But if you signal a *strong interrupt* APL halts at once, perhaps without completing execution of line 3, and in that case `⌈lc` is still 3 5.

`⌈lc` is set by APL; you can use it but not set it. The numbers in `⌈lc` are the numeric part of the *state indicator* (which shows both the name of each active verb and the current line number). See also 2 *Qws* 2 later in this chapter, and `)sl` in Chapter 12, "System Commands".

Like the state indicator itself, `⌈lc` includes an entry not only for each active user-defined verb, but also for each pending use of `⋈` or `⌊`-input. The value reported for `⋈` or `⌊` is the *line number* of the line whose sentence invoked `⋈` or `⌊` (usually, the value that appears next in the result of `⌈lc`). For example, if line 6 of *analyze* contains the phrase `⋈'x tri y'` and you interrupt execution before line 2 of *tri* has been completed, the state indicator looks like this:

```

      )sl
cri[2]*
■
analyze[6]
```

And the value of `⌈1c` is 2 6 6.

When a user-defined verb has been interrupted, the expression `→⌈1c` is commonly typed from the keyboard to mean "Resume execution with the next line in sequence." This is a shorthand for `→⌈1c(⌈1o)`, since `→` considers only the first of the values in its argument.

`⌈lib`

File Library

Monad `⌈lib` returns the names of component files located in the current directory on the drive specified in the integer argument. Drive A is 1, B is 2, C is 3, and so on. The current drive is indicated by 0.

File Permission: Any.

Result: A character table, with one row per file. Each row is a 22-element list, in which the first 10 characters are the drive number, right justified with leading blanks. The next character is blank and is followed by the file name.

`⌈load`

Load a Workspace

`⌈qload`

Load a Workspace Quietly

Monads `⌈load` and `⌈qload` have the same effect as the system command `⋄load`. Each replaces the present contents of the active workspace with the contents of a saved workspace.

The argument is a character list (or item) identifying the workspace to be loaded (optionally preceded by the number of the library to which the workspace belongs). When you do not specify a library, your own is assumed.

It is a moot question whether `⌈load` or `⌈qload` returns a result: when APL has executed `⌈load`, the active workspace in which `⌈load` was executed no longer exists.

The two forms `⌈load` and `⌈qload` differ only in whether they display the message *saved* followed by the date and time at which the saved workspace was saved. `⌈load` causes the display, `⌈qload` (*q* for "quiet") does not.

Following either `⌈load` or `⌈qload`, APL automatically executes the line it finds stored as the visible value of `⌈1x` in the workspace just loaded.

Applications that make use of `⎕load` require some mechanism to pass control from the workspace that invoked `⎕load` to the workspace loaded in consequence. Usually the invoking workspace depends upon the `⎕lx` of the new workspace to initiate action.

`⎕lx`

Latent Expression

The system noun `⎕lx` is one you may set before saving a workspace in order to control the way the workspace starts each time it is loaded. At each load, APL automatically executes the line it finds stored as the visible value of `⎕lx`, it in the same way that it would execute a line entered from the keyboard. `⎕lx` thus provides a mechanism for making an immediate and automatic start on such things as conditioning the workspace environment, starting or restarting an application, or validating a user's access to an application.

A valid `⎕lx` must be a *character item or list*. In a clear workspace, the initial value of `⎕lx` is `''`.

Whenever you load a workspace (*except* when you load it by using the `)xload` command) APL executes `⎕lx`. If a sentence stored in `⎕lx` is invalid, APL reports an error and suspends execution in the same way that it would for a sentence entered in immediate execution.

`⎕names`

Names of Tied Files

The system noun `⎕names` provides a table with the names of tied files

File permission: None needed.

Result: A character table of the file names currently tied, one file per row. The format of the result is the same as the result of `⎕lib`. Provided you do not `⎕create`, `⎕delete`, `⎕erase`, or `⎕untie` a file between invoking `⎕names` and `⎕nums`, these two nouns have their values in the same order.

□nc

Name Class of Identifiers

Monad **□nc** returns the *name class* of each of the names in ω . The argument is a table with one name per row. The result is a numeric list of classification codes, describing the visible (that is, most local) referent of each name thus:

<i>Value</i>	<i>Class</i>
0	Not in use
1	Label
2	Noun
3	Verb
4	Other

A value of four indicates that the identifier is a distinguished name (beginning with a quad symbol) or a group, or that the argument is not a well-formed name.

□nl

Name List

Monad **□nl** returns a table of names in the workspace whose visible (that is, most local) use is in a particular class. ω is a numeric item or list indicating the class of interest.

The classes that appear in the right argument are identified by the numbers 1 through 3, with the same meanings as in the result of **□nc**, above. For example, **□nl 1 2** returns a list of names whose visible use is as a label or a noun.

The result is a table, with one name per row, arranged in alphabetical order (sorted so that all first-alphabet characters occur before any of the second-alphabet characters).

Dyad **□nl** restricts the result to names whose first letter is a member of α . For example,

'XYZ' □nl 2

returns a table of the nouns that begin with X, Y or Z.

Qnums

Tie Numbers of Tied Files

The system noun **Qnums** provides a list containing the tie numbers of files currently tied. The order of the items in **Qnums** matches the order of the rows in **Qnames**.

File permission: None needed.

Result: A list of the tie numbers of files currently tied. Provided you do not **Qcreate**, **Qstie**, **Qtie**, **Qerase**, or **Quntie** a file between invoking **Qnames** and **Qnums**, these two nouns have their values in the same order.

Qpack

Build a Package

The verb **Qpack** builds a package. A *package* is a noun containing a set of *names*, a set of *name classes*, and the *referent* of each name. A referent may be a user-defined verb, a noun of any type (including a package), or *undefined*.

Dyad α **Qpack** ω forms a one-member package whose referent is the noun or pronoun ω , to which is assigned the name indicated by the character list α . (A single-character name may be represented by an item.)

For monad **Qpack**, ω is a *namelist*, that is, either a character item or list in which successive names are separated by blanks, or a table with one name per row. The result is a package containing the names of ω together with the visible referent of each name.

The representation of a verb within a package loses any function monitoring that may have been established by **Qfn**, but retains the original verb's trace- and stop-controls.

Qpdef

Package Define

Qppdef

Protective Package Define

Qpdef defines objects from within a package. For each of the names in package ω , monad **Qpdef** causes the referent within the package to replace the visible referent outside.

Dyad $\alpha \sqcap pdef \omega$ does the same thing, but only for the names included in namelist α . The namelist may be a table with one name per row, or an item or list of names delimited by blanks.

The objects thus defined replace the visible (that is, most local) referent of those names. When the name of an object to be defined corresponds to a name that has been localized in a verb that is currently executing, pendent, or suspended, the newly defined object is local, and ceases to exist when the verb to which its name is local completes execution.

Result: None for $\sqcap pdef$.

Protective Definition

The extra p in the name $\sqcap ppdef$ stands for *protective*. $\sqcap ppdef$ works in the same way as $\sqcap pdef$, both for monad and for dyad, *except* that a name is defined from within package ω only when it is not already in use outside. Thus existing uses of the names are "protected."

The result of $\sqcap ppdef$ is a table containing the names that were *not* successfully defined; when definition is completely successful, the resulting table has no rows.

$\sqcap pex$

Package Expunge

The result of $\alpha \sqcap pex \omega$ is a package containing a subset of the names in the package ω , together with their referents.

α is a *namelist* (that is, either a character list in which successive names are separated by blanks or a table with one name per row) containing names to be excluded from the result. It is not necessary that the names in α actually exist in ω .

$\sqcap pins$

Package Insert

Dyad $\sqcap pins$ merges two packages. Both α and ω are packages. The result is a package containing the union of the sets of names in the argument packages.

Where the same name occurs in both α and ω , the result takes the referent from ω . Thus everything in ω appears in the result, whereas α contributes only those names and referents *not* contained in ω .

`⊞plock`

Package Lock

`⊞plock` takes a package argument and returns a package in which verb definitions are locked.

The result of monad **`⊞plock`** is a package similar to ω in which *all* verb definitions are locked.

The result of dyad **`⊞plock`** is a package identical to ω , but in which verbs present in ω and named in α are locked. α is a namelist (that is, a character list of names separated by blanks, or a table with one name per row).

In the result, all nouns, and verbs present in ω but not named in α are unchanged.

`⊞pnames`

Package Names

Monad **`⊞pnames`** reports the names contained in package ω . The result is a table with one row for each name in ω . The ordering of names in the result is fortuitous.

When ω is an empty package, the result is a 0-by-0 table. However, when ω is not a package, the result is an empty list. The expression **`PP⊞pnames`** n thus provides a test of whether a noun n is or is not a package.

`⊞pnc`

Package Name Class

`⊞pnc` reports the name class of names in a package. The result is a numeric list, one item per name, representing the class of each name by an encoding similar to that returned by **`⊞nc`**:

<i>Value</i>	<i>Class</i>
-1	Undefined, but in package
0	Referent not in package
1	{unused}
2	Referent is noun
3	Referent is verb
4	{unused}

Monad **`⊞pnc`** returns the name class of every name in ω , in the same order as **`⊞pnames`** ω .

For dyad `Qpnc`, α is a *namelist*, that is, either a character list in which successive names are separated by blanks, or a table with one name per row. The result contains the name class of each of the names in α , in the order that they appear in α .

`Qpp`

Print Precision

The system noun `Qpp` specifies the maximum number of significant digits, or print precision, provided by the system when it displays numeric floating-point data using either default output or `v`.

You may set `Qpp` as an integer item, not less than 1 nor greater than 18; in a clear workspace, the default value is 10.

`Qpp` has no effect on the display of any value that can be represented internally as an integer, or on a number that is not different from an integer, even when represented internally in floating point. For example:

```
Qpp←3
+3
0.123

1234.000000000000001
1.23e3

1234.00000000000000001
1234
```

When `Qpp`←18, the result permits display of full internal precision, with every internal floating-point value distinguishable from its nearest neighbors. The final digit may not be otherwise significant.

`Qppdef`

Protective Package Define

See the discussion of `Qpdef`, earlier in this chapter.

□ps**Position and Spacing in Display**

The system noun **□ps** governs the formatting of an array of boxed items.

In an array of rank 2 or greater, the alignment of rows and columns is preserved by padding a narrow item to match the width of the widest item in its column, or padding a short item to match the tallest item in its row. When the display of an item requires less space than reserved for it, the first two elements of **□ps** determine its position within the rectangle assigned to it.

The second two items control the amount of additional space inserted vertically or horizontally to separate adjacent items. (These apply to any array, not just those of rank 2 or greater.) A negative value causes a box-drawing character to be placed at the vertical or horizontal edges of each box.

The effects of the four elements of **□ps** are as follows:

□ps[1] *Position in grid, first axis (vertical).*

- 1 At the top of the available space.
- 0 Centered in the available space.
- 1 At the bottom of the available space.

□ps[2] *Position in grid, second axis (horizontal).*

- 1 At the left of the available space.
- 0 Centered in the available space.
- 1 At the right of the available space.

□ps[3] *Vertical separation.*

Magnitude: the number of additional rows interpolated vertically in the result between the representations of successive rows of ω .

Vertical Box Intermarker.

When **□ps[3]** is negative and has a magnitude of at least 2, the top and bottom edges of a box are marked by `⌈` at the top of the box and `⌋` at the bottom. Where necessary, these box-edge characters overwrite the interpolated blank rows (which is why there must be at least two of them). Where necessary, the result contains extra rows at the top or bottom to accommodate box boundaries that would otherwise project beyond the outer edges of the result.

□ps[4] *Horizontal separation.*

Magnitude: the number of additional columns interpolated horizontally in the result between the representations of successive columns of ω .

Horizontal box boundaries.

When $\square ps[4]$ is negative and has a magnitude of at least 2, the left and right edges of a box are marked by | at each side. Where necessary, these box-edge characters overwrite the interpolated blank columns (which is why there must be at least two of them). Where necessary, the result contains extra columns at the left or right edges to accommodate box boundaries that would otherwise project beyond the outer edges of the result.

 $\square psel$

Package Select

The result of dyad $\square psel$ is a package containing a subset of the names in the package ω , together with their referents

α is a *namelist*, that is, either a character list in which successive names are separated by blanks, or a table with one name per row. α specifies the names to be selected from package ω (and which therefore appear in the result).

Each name in α must actually occur in ω (although it may exist there without a referent). APL rejects an expression in which a name in α does not exist in ω as a *domain error*. Monad $\square psel$ is undefined.

 $\square pval$

Package Value

Dyad $\square pval$ extracts the value of a noun from package ω . α is a character list (or item) containing a single name. The name's referent in ω must exist and must be a noun.

The result is the value of the noun α from in package ω . For example:

```
a←1 2 3
b←'Tom'▷'Dick'▷'Harry'
p←□pack 'a b'
2×'a' □pval p
2 4 6
```

`⌈pw`

Page Width

The system noun `⌈pw` sets the maximum length of a line displayed by the session handler in response to default output, or output produced by `⌈-` or `⌈-` output. A line broken because it would exceed `⌈pw` is said to be *folded*. After a fold, each continuation segment is indented by six positions. For further discussion, see the section "Display of Nouns" in Chapter 3, "Nouns and Pronouns", and the discussion of `⌈` in Chapter 5, "Verbs".

You can set `⌈pw` as an integer item not less than 30 nor greater than 250. In a clear workspace the default is 80. The current value of `⌈pw` is included when you save a workspace, and reactivated with the rest of the workspace when you subsequently load it.

`⌈pload`

Load a Workspace Quietly

See the description of `⌈load`, earlier in this chapter.

`⌈rdac`

Read File Access Table

Monad: `⌈rdac` *tn* [*,pn*]

Read file access table of file tied to *tn*, with optional passnumber *pn*.

File Permission: 256 or 4096.

Result: The three-column integer library access table of a tied file. See the discussion of access controls in Chapter 10, "APL Component Files".

`⌈rdci`

Read File Component Information

Monad: `⌈rdci` *tn*, *cn* [*,pn*]

Read component information for component *cn* of the file tied to number *tn* with optional passnumber *pn*.

The argument *tn* identifies a particular component in a particular file. The argument is a list of either two or three integers. The first contains the tie number of a tied file. The second is the number of a particular component in that file. If you specified a non-zero passnumber to tie the file, there must also be a third element containing that passnumber.

File Permission: 512.

Result: a three-element numeric list containing the following information about the indicated file component:

- (*Ordcl w*) [1] Size of the file component in bytes. The size reported includes both the data itself and the internal data description, which specifies its type, rank, and shape.
- (*Ordcl w*) [2] User that last wrote the component.
- (*Ordcl w*) [3] Timestamp when the component was written. This is not supported and will be 0.

□read

Read Component of a Tied File

Monad: *Dread* *tn, cn* [*,pn*]

Read data object in component *cn* of file tied to *tn*, with optional passnumber *pn*.

The right argument identifies a single component of a tied file. It is a list of two or three integers.

The first element contains the tie number of a tied file.

The second element contains the number of an existing component within that file. (If a component exists, its component number is less than the second element of the result of *□size*, but not less than the first.) The system rejects an attempt to refer to a non-existent file component with the message *file index error*.

The third element, when required, is the passnumber.

File permission: 1.

Result: The value of the noun stored in the file component.

□rename

Rename a Tied File

Dyad: **'newname'** □rename *tn* [, *pn*]

Rename the file tied to *tn* so its name becomes *newname*.

where *tn* is a tie number and *pn* the file passnumber (required only when you tied the file using a passnumber).

newname is a character list containing the new name proposed for the file; it must be a well-formed name, not currently in use.

File Permission: 128

Effect: The file is renamed.

Result: None.

□replace

Replace Noun Stored in a Component

Dyad: **α** □replace *tn*, *cn* [, *pn*]

Replace component *cn* of file tied to *tn*, with optional passnumber *pn*, with noun **α**.

The right argument identifies the file tie and component number, and passnumber if required. The left argument is the noun whose value is to replace the value previously stored in that component. The right argument is a list of two or three integers.

The first element contains the tie number of a tied file.

The second element contains the number of an existing component within that file; see the discussion of the second element of the argument of □read.

The third element, when required, is the passnumber.

The left argument is a noun. It may have any size, shape, or type. There is no requirement that it have the same shape or type as the noun it replaces.

Effect: The value of **α** replaces the noun stored in the component. There is no requirement that the new noun match the former value in type, rank, shape, or size.

For the system to make the replacement, *one* of the following must be true:

- The storage already in use for the file does not exceed the file's size limit

- The new component requires no more space than the old one.

File permission: 16.

Result: None.

□resize Set File Size Limit

Dyad: α □resize in [$,pn$]

where in is a tie number and pn the passnumber (required only when you tied the file using a passnumber).

α is the desired new file size limit, as a numeric item. Its value may not be less than the present actual size of the file.

Effect: The file's size limit is revised as indicated, to the next larger multiple of physical record size. As long as the actual size of the file is not greater than the limit, the file system accepts a new component or a replacement for an exiting component. Once the file's actual size exceeds the limit, the file system rejects an attempt to append, or to replace a component with a larger one, with the message *file full*.

File Permission: 1024.

Result: None.

□r1 Random Link

The system noun **□r1** is the seed value (or random link) used by the pseudo-random number generator. It is used in evaluating monadic **?** (*roll*) and dyad **?** (*deal*). Each time you invoke **?**, as a side effect the system sets **□r1**. Each time you invoke **?** with the same argument and the same value of **□r1** (and also of **□io**), you get the same result. When you save a workspace, the value of **□r1** is saved as part of it. Each time that saved workspace is loaded, the same uses of **?** yields the same results.

You may set **□r1** before executing the random function **?** to assure:

- *Same results* as on some other occasion (for example, to reproduce a test conducted earlier). For repeatable results, set **□r1** to whatever value it had before.
- *Different results* on each occasion (for example, when you repeatedly load a workspace but want to generate fresh random numbers each time). For unpredictable results, set **□r1** to something unpredictable; for example:

$$Qr1 \leftarrow (+/Qts) + x/3 + Qts + 1$$

Range and Default: You can set `Qr1` to any integer item greater than 0 and less than $2^{31}-1$. In a clear workspace, the default value is 16807 (which is 7^4).

Algorithm: As each pseudo-random number is generated, the seed (`Qr1`) is first assigned a new value and immediately used in the computation. The new value of `Qr1` depends only on the previous value, and not on the arguments of `?`. The visible value of `Qr1` is set as:

$$Qr1 \leftarrow p | m \cdot Qr1 \leftarrow p - 2147483647 \leftarrow m - 16807$$

This process is cyclic, and repeats after $p-1$ repetitions. See also the discussion of `?` in Chapter 5, "Verbs". For more information on the linear congruential algorithm used, see *The Art of Computer Programming, Volume 2: Seminumerical Algorithms*, D.E. Knuth, pages 9-10.

Qsignal

Terminate and Signal Event

The verb `Qsignal` is conditional: what it does depends on whether or not its argument is empty. Therefore it is frequently used in a conditional expression such as:

`Qsignal test/event`

Given an empty ω , `Qsignal` does nothing.

Result: None.

When ω is not empty, it must be a numeric item or one-element list. In that case, `Qsignal` causes an immediate exit from the verb highest on the execution stack (thereby cutting back the stack by one level).⁴ In response to the signal, the interpreter sets the visible value of `Qer` to record the event (just as it does from an event caused by an interrupt or an error in the definition). If a trap has been set for event ω , the trap's recovery expression takes over.

When the system sets `Qer` following a signaled event, it inserts 4 0 ω in the first four positions of row 1. On the rest of row 1, it inserts the event name. The event name is:

For dyad `Qsignal` The characters from α .

⁴Notice that this is equally true when you type `Qsignal` from the keyboard, except that there is nothing to cut back if you type `Qsignal` while no verb is pending.

For monad `⌈signal` When w is one of the standard event numbers, the standard event name (subject to `⌈nlt`) associated with w . Otherwise, blanks.

On row 2 it inserts the sentence that contains the verb whose execution was terminated by `⌈signal`. When that sentence is itself part of a user-defined verb, it shows the name of the verb and the number of the line that contains the sentence.

On row 3 it inserts a caret pointing to the name of the verb whose execution was terminated by `⌈signal`.

When there is no trap for event w , execution halts. The system displays an error message in the usual way, that is, `⌈er` with the first four characters (the event number) omitted.

See the section on event trapping in Chapter 9, "Event Handling".

Result: None.

`⌈size` Size of Tied File

Monad: `⌈size` *to* [*,pn*]

Size of the file tied to *to*, with optional pass number *pn*, returned as a the following four-element numeric list:

Result: This monadic verb returns a four-element numeric list describing the size of a file. The argument is the tie number of the file, followed (when required) by a passnumber. The elements of the list describe the file's size as follows:

- | | |
|---------------------------|--|
| <code>(⌈size w)[1]</code> | Lowest component number for this file (that is, 1 for a file from which no leading components have been dropped). |
| <code>(⌈size w)[2]</code> | Number of next component to be appended (that is, one more than the number of the last existing component). |
| <code>(⌈size w)[3]</code> | Total space now occupied by the file, in bytes. This number includes the file's internal directories, and may include dead space when a file has grown by replacing some components with components of different size. |
| <code>(⌈size w)[4]</code> | File size limit, in bytes. A request to <code>⌈append</code> or <code>⌈replace</code> with a larger record is honored only while the actual size is less than or equal to the limit. |

The number of components in the file tied to ω is given by:

$$|-/2+\Omega size \omega$$

File permission: 1 or 32768.

$\Omega stac$

Set File Access Table

Dyad: $\alpha \Omega stac \omega [,pn]$

Set access table to α for the file tied to ω , with optional passnumber pn .

The right argument is the tie number of a file followed (when required) by a passnumber.

The left argument is the proposed access table. It is a three-column table of integers. See the discussion of access tables in Chapter 10, "APL Component Files".

Effect: The left argument α becomes the access table for the file tied to ω .

File Permission: 8192 or 256.

Result: None.

$\Omega stie$

Share Tie

Ωtie

Exclusive Tie

Dyads $\Omega stie$ and Ωtie establish linkage between the name of an APL component file and the tie number used to refer to it from the active workspace. $\Omega stie$ permits other users to share the file at the same time (whereas Ωtie is exclusive). On a single user system $\Omega stie$ and Ωtie have the same effect.

'filename' $\Omega stie \omega [,pn]$

The right argument is integer, containing the proposed tie number, followed (when required) by the passnumber called for in the file's access table.

The proposed tie number must be a *positive integer less than 2^{31}* and not in use as a tie number of another file.

When the right argument has two elements, the second is the passnumber. When the argument is a scalar or one-element vector, a passnumber of 0 is understood.

The left argument is a character list (or item) containing the name of an existing file.

Watch out: It is poor practice to have the tie number appear as a *constant* in your programs. It is preferable to generate a tie number arbitrarily and then store it somewhere that the verbs requiring it can find it; for example, as a global noun in the workspace.

Effect: The file is tied. You may proceed to use the file.

File permission: Any.

Result: None.

⌈trap

Event Trap Control

By setting the value of the system noun ⌈trap, you specify the action to be taken if various events should occur. Events include errors, interrupts, and return to immediate execution. See also Chapter 9, "Event Handling".

⌈trap is shared with the interpreter. In general, you set its value and the interpreter uses it. (However, the interpreter acts to "" any value that is syntactically invalid.)

⌈trap may be either a table or a list. When it is a table, it has one row for each trap definition. When it is a list, the first character serves as a delimiter, and subsequent uses of the delimiter serve to separate the various definitions. The delimiter may not be a numeral, a blank, or the character -, which has a special use in the events field.

In general, each trap definition (that is, each row of a table ⌈trap, or each of the definitions separated by the delimiter in a list ⌈trap) has the following form:

List of event numbers	Qualifier	Action	Recovery expression
-----------------------	-----------	--------	---------------------

The successive fields within a trap definition need no delimiter between them, but may be separated by any number of blanks. The fields are filled out as follows.

□trap Event Numbers Field

Events are identified by numerals. Successive numbers are separated by blanks, for example 2 14 5. The order in which events are listed does not matter. A hyphen means "all events" in a range of numbers. For example 1-11 means "Events 1, 11, and all events in between." Figure 16-4 shows all event numbers currently defined by APL.

0 means any event less than 1000; it has the same effect as 1-999. Setting a trap for 1000 applies to any event greater than 1000 and less than 2000; it has the same effect as 1001-1999. Where *no* numbers are stated, the trap definition applies to *all* events other than event 2001.⁷

□trap Qualifier Field

Either this field is empty, or it contains the letter *o*. The presence of an *o* makes the trap operate only at the verb's own level. That is, the trap works in the verb to which □trap is local, but not in verbs invoked within it.

Note that *o* may be needed because, when verbs invoked within the current verb also localize □trap, they may nevertheless fail to trap an event. Unless the *o* qualifier is included, this □trap may respond to an event that occurs in one of the sub-verbs.

Watch out: You must separate the qualifier from the surrounding trap definition by *at least one space*.

□trap Action Field

The action is indicated by a single letter, as follows:

<i>s</i> <i>Stop</i>	Preempts other traps, if any.
<i>n</i> <i>Next</i>	Exempts the current trap, leaves more global ones in effect.
<i>e</i> <i>Execute</i>	Executes the recovery expression in the current environment.
<i>c</i> <i>Cut and execute</i>	Cuts back the state indicator, then executes.
<i>i</i> <i>Immediate</i>	Resumes in mid-line (after the recovery expression has supplied the missing name).
<i>d</i> <i>Do</i>	One of four drastic measures. (See below.)

⁷Whether it applies to events 67 and 68 is moot; when they really occur, there is not much you can do about them. The trap does apply, however, if you [signal] those events. [Signal] of these events is not recommended, however - it tends to confuse support staff and send them looking for system problems rather than application problems.

⌈trap Recovery Expression

The recovery expression is a line of APL in the same form as you might type it from the keyboard or assign it to ⌈lx.

In particular, with action *e* and *c*, if you want execution of the suspended verb to be resumed, you must include the branch arrow →. However, with action *i* (where the recovery expression supplies the definition of an undefined name) execution resumes at once when the name is defined, and the recovery expression should *not* include a branch arrow.

If the recovery expression itself contains an error, that error cannot be trapped, and execution halts.

The trap actions and their associated recovery expressions are listed in the following sections.

Action *s* : Stop

Stops execution when an event occurs. This action takes no recovery expression. In effect, it restores the default action of the interpreter, and is often used during debugging.

Note that setting ⌈trap←'n s' is stronger than ⌈trap←'' because making the visible ⌈trap empty does not remove the action of other traps that may be shadowed.

Action *n* : Next

The action *n* instructs the interpreter to look no further in the present ⌈trap, but to move on to the next (more global) ⌈trap. It has the effect of nullifying trap definitions in its own ⌈trap that appear later in the trap definition.

Like *s*, action *n* takes no recovery expression.

Action *i* : Immediate

Action *i* is usable only with event 6, value *error*. It is designed to supply the value of the undefined name and resume execution. A common use of this action is to implement demand paging systems.

Action *i* is the only action that permits resumption of an interrupted line at a point other than the beginning.

Action *i* requires a recovery expression. The recovery expression must *not* include a branch statement. It should do something to remedy the fact that an undefined name occurs in the sentence being executed (for example, read its definition from a file).

When the recovery expression has been executed, the interpreter tries to resume execution of the sentence it was executing when it found an undefined **NAME**.

If the name is *still* undefined after execution of the recovery expression, event 6, value error is signaled again, but the *i* action will not act upon it.

Action *e* : Execute

The interpreter executes the recovery expression in the current environment. To resume work after completing the remedial action, the recovery expression should include a sentence such as `~[i]c`.

Action *c* : Cut Back and Execute

The interpreter aborts the execution of any verbs invoked by the verb that localized `[i]trap` (thereby cutting back the state indicator so the verb to which `[i]trap` is local is at the top), and then executes the recovery expression.

Action *c* differs from action *e* only when the operative trap is more global than the verb being executed. Especially where the recovery expression uses a branch to resume execution, it is usually necessary to use action *c* rather than *e*. That is because the recovery expression is usually written as a branch to a destination that makes sense only in the verb that set the `[i]trap`. For example, if verb *v1* has a trap whose recovery expression is

`fixup ⚡ →retry`

the destination `retry` is perhaps a label on line 6 of *v1*. If verb *v1* invokes *v2* and *v2* encounters an event which this trap traps, the effect with action *e* might be to go to line 6 of *v2*, when what you really want is to resume at line 6 of *v1*.

Action *d* : Do

This action invokes one of several actions that are not directly attainable by executing an APL sentence (and hence not obtainable from actions *e* or *c*). In addition, action *d* is the only action permitted in response to event 2001 (return to immediate execution), which is not otherwise a trappable event.

The recovery expression may be empty, or may contain one of the following keywords:

`exit` `clear` `off`

These actions have the following effects:

- d* Action *d* with no keyword has no effect, other than to handle the event and thus prevent more global `⌈traps` from being searched.
- d exit* Causes execution to exit from the verb that contains the `⌈trap`, and return to the environment in which that verb was invoked.
- d clear* Clears the workspace. The former contents are lost.
- d off* Clears the workspace and terminates the APL session. The action *d off* terminates the APL task without saving a *continue workspace*, whereas `⌈bounce` saves *continue*.

`⌈ts`

Timestamp

The system noun `⌈ts` contains the current date and time of day (represented by the computer's internal clock) as a seven-item *numeric list* containing the following information:

<code>⌈ts[1]</code>	Year
<code>⌈ts[2]</code>	Month
<code>⌈ts[3]</code>	Day
<code>⌈ts[4]</code>	Hour
<code>⌈ts[5]</code>	Minute
<code>⌈ts[6]</code>	Second
<code>⌈ts[7]</code>	Millisecond

The first three elements of `⌈ts` always indicate a date, and the last four elements always indicate a time of less than 24 hours.

`⌈ul`

User Load

This system noun reports 1 as the number of APL tasks.

□untie

Untie Tied Files

Monad **□untie** unties the files whose tie numbers are included in its argument. ω is a numeric list (or item) of numbers currently in use to tie files. Passnumbers are *not* included in ω .

The right argument is a numeric list (or item) of tie numbers.

Passnumbers do not apply to **□untie**. You do not include a passnumber even if you did specify one to tie the file. Any number appearing in the right argument ω is assumed to represent a tie number.

Effect: The files whose tie numbers appear in ω are untied. Once you have untied a file, when that tie number appears in the argument of a file verb, the file system rejects the sentence with the message *file tie error*. There is no way to refer to the files that were untied until you subsequently re-tie them.

File permission: None.

Result: None.

□vi

Verification of Input Format

Monad **□vi** reports whether each field in ω is a valid numeric field.

ω is a character list (or item). **□vi** treats ω as a sequence of fields, in the same fashion as **□fi** (described earlier in the chapter).

The result is a Boolean list containing a 1 for each field that represents a well-formed number, and 0 for each field that does not.

□vi can be used in conjunction with **□fi** to provide a validity check on the input character list, as described in the discussion of **□fi**.

□wa

Work Area Available

The system noun **□wa** is a numeric item indicating the current amount of work area available in the active workspace (in bytes). It is computed by subtracting from the gross size allocated to the workspace the amount currently in use for the definitions of nouns and verbs, the symbol table, and the execution stack and partial results associated with it.

□WS

Workspace Information

Dyad □WS reports a number of different items of information about the current state of the workspace. The information returned in the result depends on the values of the two arguments, each of which is a numeric item. The possible values and the results associated with them are as follows:

- 1 □WS ω *Nameslists*. ω is a numeric item identifying the class or classes of names to be included in the result.* ω must be a single item whose value is the sum of the numbers representing the desired classes. The classes are identified by powers of 2:

- 1 Verb
- 2 Noun
- 4 Group
- 8 Label

The result is a character table containing one row for each visible name in any of the classes identified in ω.

- 2 □WS 1 *Workspace ID*. The result is a character list containing the name of the active workspace. When the workspace has not been named, the list is empty. Otherwise, it has 22 characters, in the same format as returned by □LIB for the names of files. Although the format differs slightly, the information conveyed is the same as that displayed by the command)WSID.
- 2 □WS 2 *State indicator*. The result is a character table containing one row for each item on the state indicator, in the same format as displayed by the command)SI. Each row contains the name of a user-defined verb, followed by a line number in brackets. A verb that is suspended is marked by an asterisk following the closing bracket of the line number. The line number is the number of the line currently active (for a verb that is not suspended) or the number of the line next to be executed (for a verb that is suspended). The rows of the table show the most recently invoked verbs at the top. Calls to a or □ input are shown in the result in the same way as user-defined verbs; each has a row on which the symbol a or □ appears alone.
- 2 □WS 3 *Workspace environment*. The result is a 12-element numeric list. A number of its elements are no longer in use and contain -1 or 0, but are preserved to maintain consistent position for the

* The effect of 1 □WS ω is essentially the same as that of □N1. In both cases, ω identifies the classes to be included in the result, but 1 □WS identifies them by a scheme different from that of □N1.

others. The meaning of an element at each position in the result is as follows:

- (2 Dws 3)[1] Unused.
- (2 Dws 3)[2] Unused.
- (2 Dws 3)[3] Effective workspace size. This reports the actual workspace size in bytes that is under the control of the APL application. This is useful information in the implementation of demand-paging schemes for APL objects in the workspace.
- (2 Dws 3)[4] Unused.
- (2 Dws 3)[5] Unused.
- (2 Dws 3)[6] Unused.
- (2 Dws 3)[7] Current size of the symbol table.
- (2 Dws 3)[8] Symbols in use.
- (2 Dws 3)[9] Unused.
- (2 Dws 3)[10] Unused.
- (2 Dws 3)[11] Unused.
- (2 Dws 3)[12] Unused.

2 Dws 4 *Workspace information.* The result describes the workspace by a three-element numeric list:

- (2 Dws 4)[1] Bytes needed to store the contents of the workspace.
- (2 Dws 4)[2] Unused.
- (2 Dws 4)[3] Timestamp as 60ths of a second since 1960-03-01 00:00:00.

3 Dws ω *Group members.* ω is the name of a group. The result is a character table containing the names that are members of the group.

4 Dws ω *Storage space.* The number of bytes of workspace storage required to store each of the objects named in ω . ω is a namelist, either a list with successive names separated by blanks, or a table with one name per row. The result is the number of bytes that would be required to store the named object if it were the only instance in the workspace. (In fact, an object may be stored merely by pointing to another instance of the same value). The value includes space occupied by the header that the interpreter uses to describe the object's type, rank, and shape, but not the

space occupied by the entry for its name in the symbol table. If a name is that of a shared name, the result does not constitute a reference to the name.

- 5 **Qws ω Name class by stack level.** ω is a namelist, formed either as a list with successive names separated by blanks, or as table with one name per row. The result is a *numeric table*, having one row for each name in ω , and one column for each level of the state indicator, plus an additional final column representing the global environment (not represented in the state indicator). Values within the result as follows:

- “1 Not localized at this level
- 0 Localized at this level, not used
- 1 Localized at this level, used as a verb
- 2 Localized at this level, used as a noun
- Group
- 8 Localized at this level, used as a label

- 6 **Qws ω Noun Value.** ω is the name of a noun. The result is the value of the noun, or *domain error* if the name is not that of a noun. If the name is a shared name, it does not constitute a reference to the name.

12 System Commands

System commands begin with a right parenthesis `)`, followed by the name of the command and any arguments. Command names may be spelled in either the first or second alphabet (that is, lowercase or capitals).

You may enter a system command only when the interpreter is in immediate execution mode (including `□`-input mode). You may not execute a system command from within the `□`-editor. A system command may not be part of a user-defined verb.

<code>)clear</code>	Clear workspace
<code>)continue</code>	Save <i>ws</i> for resumption, and sign off
<code>)copy ws [:pass] [nm₁, nm₂, ...]</code>	Copy from saved to active <i>ws</i>
<code>)drop ws [:pass]</code>	Discard saved workspace
<code>)erase [name₁, [name₂, ...]]</code>	Erase global objects
<code>)fns [firstname]</code>	List verbs (starting with <i>firstname</i>)
<code>)group grpname [name₁, name₂, ...]</code>	Form or disperse a group
<code>)grp grpname</code>	List members of a group
<code>)grps [firstname]</code>	List groups (starting with <i>firstname</i>)
<code>)lib [drive]</code>	List workspaces
<code>)load ws [:pass]</code>	Load and activate saved workspace
<code>)off</code>	Terminate session
<code>)pcopy ws [:pass] [name₁, name₂, ...]</code>	Protected copy from saved to active <i>ws</i>
<code>)reset</code>	Synonym for <code>)sic</code>
<code>)save [ws] [:pass]</code>	Save a copy of the active workspace
<code>)si</code>	State indicator
<code>)sic</code>	State indicator clear
<code>)sinl</code>	State indicator with namelist
<code>)siv</code>	Synonym for <code>)sinl</code>
<code>)symbols [n]</code>	Size of symbol table
<code>)vars [firstname]</code>	List nouns (starting at <i>firstname</i>)
<code>)wsid [newname]</code>	Save-name of the active workspace
<code>)xload ws [:pass]</code>	Load workspace without executing <code>□lx</code>

Figure 12-1: List of system commands.

)clear**Clear Active Workspace****)clear**

Clears the active workspace and sets all system nouns to their default values.

Conditions in a Clear Workspace

Clearing the workspace restores several parameters to their default values. These are summarized in Figure 12-2.

<i>Parameter</i>	<i>System Noun</i>	<i>Value</i>
Comparison tolerance	<code>⓪ct</code>	1.4196976927394189e ⁻¹⁴
Format control	<code>⓪fc</code>	' , , ** _ '†
Index origin	<code>⓪io</code>	1
Line counter	<code>⓪lc</code>	10
Latent expression	<code>⓪lx</code>	''
Tie numbers in use	<code>⓪nums</code>	Unaffected
Names of tied files	<code>⓪names</code>	Unaffected
Printing precision	<code>⓪pp</code>	10
Position and spacing	<code>⓪ps</code>	~1 ~1 0 1
Page width	<code>⓪pw</code>	80
Random link	<code>⓪rl</code>	16807
Work area available	<code>⓪wa</code>	As set by system startup
Shared names		None; previous offers are retracted
Symbol table		Space for 256 symbols (can vary with space available)
Workspace name		None; reported as <i>clear ws</i>

Figure 12-2. Conditions in a clear workspace.

)continue

Terminate APL Session for Restart

`)continue`

Terminates APL and saves the active workspace under the name `continue`.

)copy

Copy Objects into Workspace

`)copy ws [:pass] [name1 name2 ...]`

)pcopy

Protected Copy into Workspace

`)pcopy ws [:pass] [name1 name2 ...]`

Copies objects from the saved workspace `ws` into the active workspace.

When no other names follow `ws`, all global user-defined names in the saved workspace are copied, but not system nouns. When other names follow `ws`, only the objects named are copied, and the list may include system nouns.

For `)pcopy`, global objects already in the active workspace are *protected*; that is, they remain as they were. If any objects were protected in this way, APL displays the message *not copied*: followed by a list of the names of objects that were not copied.

Note that `)copy` and `)pcopy` deal with global objects only. They cannot copy the values of names that are localized in the saved workspace, and the values that materialize in the active workspace are global as well.

)drop

Delete a Workspace

`)drop ws [:pass]`

Discards the saved workspace named `ws` from storage. The active workspace is unaffected, and so is its name (which may be the same as the name of the workspace thus dropped). APL reports the date and time at which you dropped the workspace. If the workspace is locked, you need its password in order to drop it.

When you know you want to drop a locked workspace, but you cannot remember the lock, the following will serve:

```
)clear  
)wsid lockedws  
)save  
)drop lockedws
```

)erase

Erase Global Objects

```
)erase [name1 ] [name2 ...]
```

This command erases (expunges) the *global* definitions of the user-defined objects named in the list to the right. When an argument to `)erase` is the name of a group, both the group *and* all members of the group are erased.

APL reports only the names of those objects explicitly mentioned in the argument that it did *not* erase. It displays their names in one or two messages, with the captions *not found*: or *not erased*:, as appropriate.

An object is not erased if its name:

- is not the name of a global object
- refers to an verb in the state indicator)
- refers to a system noun

)fns

Display Verb Names

```
)fns [firstname]
```

This command displays a list of names whose visible referent is a user-defined verb (function), in alphabetical order, horizontally across the screen. For alphabetization, a collating sequence is assumed in which all first-alphabet letters precede any second-alphabet letters.

When the command is followed by a name, the list shows only those names that occur in the alphabetized list at or after the position of that name.

The names listed are the same as those returned in the result of `[n] 3` or `1 [ws 1]`.

)group

Alter a Group

)group *grpname* [*name₁* *name₂* ...]

This command forms or disperses a group. When you form a group, the first name is the name the group is to have, and the names that follow are the names of its members.

A group provides a shorthand way of referring to a set of global names, primarily so they can be either copied or erased without having to mention them individually in the argument to the command **)copy** or **)erase**.

To add new members to an existing group *grpname*, the syntax is:

)group *grpname* *grpname* *newname₁* *newname₂* ...

)grp

Display Group Member Names

)grp *grpname*

Returns the list of names that are members of the group *grpname*.

)grps

Display Names of Groups

)grps [*firstnames*]

Returns names of all groups in the active workspace.

)lib

Display Saved Workspace Names

)lib [*drive*]

Displays the names of saved workspaces in the current directory on the specified drive. The argument is 1 for drive A, 2 for B, 3 for C, and so on.

)load

Activate a Workspace

)load ws [:pass]

Replaces the current active workspace by a duplicate of a saved workspace. The former contents of the active workspace are lost.

The new contents must fit within the size of the active workspace.

Following the **)load** command, the interpreter immediately executes the latent expression stored as the visible value of the system noun **⌈ix**.

The)xload Variant

The variant command **)xload** is similar to **)load**, except that the interpreter does *not* execute the latent expression. This is intended as a convenience in doing maintenance.

)off

Terminate APL Session

)off

This command terminates the APL session.

)pcopy

Protected Object Copy

)pcopy

See **)copy**.

)reset

Clear SI Stack

)reset

This command is a synonym for **)sic**, described below.

)save

Save Active Workspace

`)save[ws] [:pass]`

This command saves a copy the active workspace.

When you load a saved workspace, the active workspace has the same name as the saved workspace. The active workspace resulting from the command `)clear` has no name. You may give your active workspace a name by the command `)wsid`. The name of the active workspace is a *potential* name. That is, it is the name under which APL would save your active workspace if you execute the command `)save`. When the workspace as yet has no name, APL rejects the command `)save` with the message *not saved, this ws is clear ws*.

If you try to assign a new name that duplicates the name of an existing saved workspace, it is rejected with the message *not saved, this ws is XXX*, where XXX is the existing name of the active workspace.

After the `)save` command is successfully carried out, the name under which you saved it becomes the name of the active workspace.

Workspace Locks

When you save a workspace, you may *lock* it. A locked workspace has a *password* of up to eight letters and/or numerals. You lock a workspace by entering a colon and the proposed password at the end of the `)save` command. Once a saved workspace has been locked, anyone (including you) making reference to the saved workspace or its contents must include a colon and the password in the command.

)sic

State Indicator Clear

`)sic`

This command abandons execution of *all* suspended and pendent verbs, thereby clearing the state indicator. The referent of any local name is lost.

The effect of this command is different from that produced by the naked branch `-`. The branch abandons execution of the verb most recently started from immediate execution, together with all verbs that it may have invoked, but has *no* effect on verbs whose execution started earlier than that. See also `⌈trap` action `d`.

)si

State Indicator

)siSee **)siv**.**)sinl**

State Indicator with Namelist

)sinlSee **)siv**.**)siv**

State Indicator with Namelist

)siv

This command causes APL to display a list of the verbs whose execution is pending or suspended, and which are therefore on the execution stack (or *state indicator*). The list shows each level of execution on a separate line, showing the name of the verb and the number of the line that is currently active.

For a verb that is *suspended*, the display shows an asterisk. The line number in that case is the number of the line next to be executed when execution is resumed.

To illustrate, consider the following display:

```
      )si
get[4] *
verify[1]
mean[1] *
analyze[3]
report[2]
```

The verb *get* is suspended, and has not completed execution of line 4. If resumed, it would start at the beginning of line 4. The verb *get* was invoked by line 1 of *verify*. The verb *verify* is waiting for *get* to complete, at which point *verify* will resume automatically its work on the line indicated (line 1).

The verb *mean* is also suspended. Evidently, following that suspension, rather than resume its execution, you invoked *verify* (perhaps in an effort to examine the cause of the interruption in *mean*).

mean was invoked by a sentence on line 3 of *analyze*, which in turn was invoked by line 2 of *report*. *report* must have been invoked in a sentence entered from the keyboard during immediate execution.

The verb *a* or a request for input via *□* appears in the state indicator in the same way as a user-defined verb, but without a line number.

A table having the same appearance as *)si* is returned as the result of the verb 2 *□ws* 2. A list of the line numbers that appear is returned by the verb *□lc* (for *line counter*).

Optionally, the command may include the letters *nl* (for *namelist*), so that it is written *)sinl*. In that case, the display is organized in the same way, but also includes on each line a list of names local to the verb on that line. The information about the use of names is returned in a different form by the verb 5 *□ws*.

The obsolescent form *)siv* (state indicator with variables) is still accepted as a synonym for *)sinl*.

)symbols

Set Symbol Table Size

)symbols [*n*]

Used without an argument, this command reports the current size of the symbol table. The symbol table must contain an entry for every name in the workspace, including the name of every user-defined noun and verb. It also contains every name referred to in a definition that exists in the workspace.

Used with a numeric argument, this command causes the interpreter to set aside space in the workspace for a symbol table with the number of entries requested. (You may not request a table smaller than the number of names already in use; such a request is rejected with the message *symbol table full*.)

Since APL is able to increase the size of the symbol table automatically, it is not essential to do this. However, to avoid some inefficiencies in having to resize the table dynamically, it may be desirable to set the size large enough to accommodate all foreseeable names. Conversely, when you know that few names are needed, you can make the symbol table smaller and thereby recover some of the space that would otherwise have been reserved for it.

The symbol table size and number of symbols in use are also reported by 2 *□ws* 3.

)vars

Display Noun Names

)vars [*firstname*]

This command causes APL to display a list of those names whose visible referent is a noun (variable), in alphabetical order, in the same format as **)fns**. The names are the same as those returned by **(In) 2** or **1 Dws 2**.

)wsid

Set Workspace Name

)wsid [*newname*]

Used with no argument, **)wsid** displays the name of the active workspace.

Used with an argument, **)wsid** assigns that name to the active workspace. The name of the active workspace is relevant only when you subsequently save the workspace.

Watch out: If you set the name of the active workspace to the name of an already-saved workspace, you defeat APL's check against overwriting one of your saved workspaces.

)xload

Load Workspace without Autostart

)xload

See the entry accompanying the description of **)load**.

13 Messages

When for some reason the APL system encounters a problem and cannot proceed, it may display a message to indicate what has happened. This chapter describes what the various messages mean, the circumstances that may have produced them, and in some cases what remedial action you may be able to take.

Sources of Messages and Trouble Reports

Trouble reports regarding system commands

A trouble report describes a problem encountered in attempting to carry out a system command or involving the V-editor.

Error or interrupt messages from the APL interpreter

Each of these messages is caused by an event detected by the APL interpreter. The event is either an error in a line being executed or an interrupt signaled from outside the workspace (usually from the keyboard) while a line is being executed. Some (but not all) errors or interrupts can be intercepted by an appropriate setting of `Trap`, and are said to be *trappable*.

Trappable Errors and Interrupts

Each time a trappable event occurs, the system sets a new value for the system noun `Err` (*event report*). If the event is *not* trapped, execution halts, and the system displays a message. The message is identical to the content of `Err`, except that `Err` also contains an event number while the display does not.

Following an untrapped error or interrupt, it may be possible to take corrective action. If the message is in response to an entry from the keyboard, you may be able to correct the entry and resubmit it. If the message is in response to a problem that arose during execution of a user-defined verb, you may be able to correct the situation and resume execution.

Form of an Error Message

When the APL interpreter encounters an untrapped error or interrupt, it sends you a three-part message. The first part is a general description of the type of problem (for example, *syntax error* or *value error*). Then it shows you the line containing the error. If the line is within a user-defined verb, it shows also the name of the verb and the number of the line on which it was working when it encountered the error. (When the verb's definition is locked, the system shows the verb's name and the line number, but not what is on the line.)

Below that, on the third line, the system displays a caret. The caret points to the part of the line on which the interpreter was working when it encountered the error. For some errors, the system can point quite precisely to what is wrong. For others, it is harder to point to what is wrong. For example, if you omitted a parenthesis, it is hard for the system to know where you should have put it. Instead, it shows where it was working when it found that parentheses do not match.

How Much Has Been Executed

When the system displays a line of APL marked with a caret, the interpreter may have already executed part of the line, before it discovered the error. In general, you can tell what has been executed by the position of the caret. But it is prudent to check further; the caret's position is not a definitive guide. An approximate rule is:

- A *syntax error* due to mismatched quotes, or inclusion of illegal characters as part of an unquoted part of a line, is signaled before any part of the line is executed. The caret appears one character past the right-most end of the line.
- Within a *line* containing diamonds, statements to the right of the caret have *not* yet been executed.
- Within the *sentence* to which the caret is pointing, verbs to the right of the caret *have* been executed.

If the statements or verbs that have already been executed produce some lasting change (for example, by respecifying the value of a noun or of a file component), you may have to make allowance for that before you re-execute the line.

Error Messages By Event Number

This section lists the numbered "events" in order of event number. For each event, it shows the associated message in English, French, and German.

1 `ws full`

If the system were to execute the verb, or to copy the requested objects, it would require more space than is available in the workspace.

Remedy: Sometimes it suffices to erase unwanted objects in the workspace. If the workspace contains suspended or pendent verbs, `)sic` or `+` may help. Alternatively, you may need to alter the algorithm so that its intermediate storage is not so extensive. (When this condition arises as the result of executing an APL expression, it is trappable as event 1. But `ws full` arising during `)load`, `)copy`, or `)save` is not trappable.)

2 `syntax error`

The syntax analyzer has detected a statement appearing to violate the syntactic rules of the language. This could be for any of several reasons; for instance

- You have invoked a verb requiring a right argument without one.
- You have unbalanced parentheses, brackets, or quotes.
- You have juxtaposed two names referring to nouns with no indication of a verb to be applied to them.

3 `index error`

Within the brackets delimiting an index or axis, you have supplied a value that is not a valid index for the object being indexed. One possible cause of the problem is the wrong setting for the system noun `Q10`.

4 `rank error`

You have invoked a monadic verb whose argument is limited to a particular rank with an argument of some other rank. Or you have executed a dyadic verb with arguments not corresponding in rank when they should.

5

length error

You invoked a dyadic verb requiring its arguments to match in length, but your arguments do not match along the required axes.

6

value error

You have referred to what appears to be the name of a noun or verb with no visible value. This might be because the name is shadowed during execution of a verb, or because the value really does not exist in the workspace. This message often arises because you have misspelled the name of the noun or verb.

7

format error

You have supplied an invalid argument to `Qfmt`. The system displays the portion of the left argument of `Qfmt` that it was attempting to interpret.

8

result error

An expression produced no result (in a context in which a result is expected). `⌘` and monadic `→` produce no result; neither does a user-defined verb whose header does not include a name for the result, or whose execution ends without ever assigning a value to the result.

■

si error

You have changed the definition of a suspended verb in a way that changes the use of names so that APL cannot find the definition of a pendent verb.

Remedy: Clear the state indicator by executing `→` as needed, or clear the state indicator completely by the command `)sic`.

11

domain error

You have invoked a verb, but the arguments you supplied to it are outside the verb's domain. Common examples: you have tried to divide by zero, or to concatenate numbers and characters, or you have supplied a fractional argument to a verb defined only on integers. Consult the description of the verb in question for the criteria for an acceptable argument.

15
symbol table full

The line you are trying to execute, or the package whose contents you are trying to define, or the object you are trying to copy, requires the use of names for which there is no space in the symbol table, and the symbol table can no longer be automatically resized. This can only occur if the symbol table is already at its maximum size.

Remedy: Correction will require resizing the workspace or reorganizing the application so that either a larger symbol table is possible or the need for so many distinct symbols is reduced.

16
nonce error

The expression you entered appears valid, but APL is not presently (that is, for the nonce) equipped to execute it. This message may be encountered if you execute a proposed verb that the system recognizes but whose implementation is not yet released.

18
file tie error

You have specified a tie number as if it were tied when in fact it is not, or as if it were free to be tied when in fact it is already tied.

19
file access error

You have tried to tie a file to which you do not have access, or to tie or use it without the correct passnumber, or to use it with a verb for which the file's access matrix does not give you authorization.

20
file index error

You have invoked `Qread`, `Qreplace`, `Qrdcl`, or `Qdrop` with an argument referring to a nonexistent file component, or you have attempted to append a component number greater than 214748647 to a file.

21
file full

You have attempted to append a new component to a file whose current size already exceeds the number of bytes reserved for that file.

Remedy: Resize the file. See the description of `Qresize` in Chapter 11, "System Nouns and Verbs".

Note: You might expect that replacing some of the existing components with data requiring less space would decrease the total storage of the file. While that is true in the long run, it does not always reduce the total size immediately. That is because the physical storage freed by doing that may not be available to the new components you want to append until after the operations staff has performed periodic file maintenance.

22

file name error

The left argument of `⌈tie`, `⌈stie`, or `⌈create` is not a valid name, or, where the verb must refer to an existing file, not the name of an existing file. In the case of `⌈create`, the file name may already exist.

23

file damaged

The file you are trying to use has been marked *damaged*.

24

file tied

You have attempted to tie a file you have already tied.

25

file system hardware error

The system is unable to read correctly from the physical device storing the component you have asked to read or write.

26

file system error

Something is seriously wrong with the file.

28

file system not available

You have invoked a file verb other than `⌈avall` when the file system is not running.

30

file system ties used up

The system has tied the maximum allowed number of distinct files.

Remedy: Untie files that you are not currently using.

31
file tie quota used up

The system has tied the maximum allowed number of distinct files.

Remedy: Untie files that you are not currently using.

38
file component damaged

You have attempted to read a file component that is unreadable because of an inconsistent file system internal directory.

45
ws locked

While referring to a workspace, the password you have supplied does not match the password with which the workspace was saved. This could arise either because the workspace requires a password but you did not supply the right one, or because it has no password and you did supply one. If your reference to the workspace occurred in an APL expression (that is, one invoking `ⓘload` or `ⓘgload`), this event is trappable as event 45. But if your reference was in a system command, it is not trappable. (When this happens following a command `)load` or `)copy`, `ⓘer` is not set. But when it happens in response to `ⓘload` or `ⓘgload`, `ⓘer` is set to show event 45.)

■
ws not found

The workspace you requested does not exist. If your reference to the workspace occurred in an APL expression, this event is trappable as event 46. But if your reference was in a system command, it is not trappable.

47
ws not readable

The system is unable to read the saved workspace.

68
system error, clear ws

The system has encountered an undiagnosed error while executing a command or an APL statement in your workspace and the system clears your workspace.

72

interface quota exhausted

You have attempted to offer to share more names at one time than the APL system allows.

Remedy: Retract some shares.

73

no shares

You have invoked a shared name verb when the system's Shared Variable Processor is not running.

74

interface capacity
exceeded

You have attempted to assign to a shared variable a value requiring more storage space than the system's Shared Variable Processor can accept.

System Nouns with Invalid Values

The following events arise when the indicated system noun has been given an unacceptable value. (See the description of the noun in question in Chapter 11, "System Nouns and Verbs".)

78
□pp error

79
□pw error

80
□io error

81
□rl error

82
□ct error

84
□ps error

85
□fc error

95
ws not writable

You have attempted to)save a workspace, but a hardware failure has prevented it from completing successfully.

Interrupt Events

1001

stop

While executing a user-defined verb, APL has encountered a line for which a *stop* has been set (see "Stop and Trace Controls" in Chapter 8, "Control of Execution").

1002

attention

While executing a user-defined verb, APL has received a *weak interrupt*. Execution halts at the beginning of the next line to be executed.

1003

interrupt

The system has received a *strong interrupt* signal. It has cut short execution of the line it was executing.

Watch out: Part of the line may have been executed. An instruction to store data occurring within this statement and to the right of the caret may have been carried out already. That includes assigning a new value to a noun or storing something in a file. If you consider re-executing the line, notice that that storage (noun or file component) may already have received a new value, and the line may not be trivially re-executable.

The system discriminates several different interrupts, according to the interrupted activity:

1004 Interrupt during □- or □-input.

1005 Interrupt while awaiting a shared name access.

1006 Interrupt during a file operation.

1007 Interrupt during file backup.

1003 An interrupt during execution, but not 1005, 1006, or 1007.

1004

input interrupt

You have interrupted input from the keyboard (in response to □ or □).
